Another group of problems related to traffic simulation originates from the lack of communication and understanding between teams of engineers and decision makers regarding the use of traffic simulation. Examples of this divergence include different objectives, needs, and exploitation plans for the traffic simulation models. For example, the pressure for quick results might lead to compromise in the calibration and validation process, thus leading to unreliable results that can jeopardize the validity of the traffic simulation results.

Traffic Studies and Surveys

This entry discusses the surveys that inform traffic and transportation analysis models and provide basic inputs for running and calibrating these models. Apart from being a feeder mechanism for transportation models, traffic surveys provide data

for road engineering interventions and for assessing the synergies between urban-transport planning, regional, economic, environmental, and social development sectors.

Traffic studies are based on the various surveys carried out as an integral part of the entire urban-transport planning process. Traffic surveys consist of a set of surveys conducted at different scales (for example, regional, city, area, or intersection) and for different entities (for example, users, operators, municipal urban planning authorities, or road authorities) as determined by the requisite data need. Most of the traffic surveys consist of quantitative data collection techniques, which are increasingly being supplemented by qualitative data.

Traffic surveys range from preliminary reconnaissance surveys to detailed data collection surveys, and offer a holistic overview of the various parameters that dictate the traffic conditions of a given place. The most important primary traffic surveys are inventory or reconnaissance surveys, traffic-flow surveys, speed surveys, travel-time and delay surveys, origin-destination surveys, intersection-turning-movement surveys, parking-use surveys, environmental-impact surveys (for example, noise impact surveys or air quality surveys), user surveys (for example, public-transport-user surveys, cyclist surveys, or pedestrian surveys), operators surveys, household surveys (for example, socioeconomic and travel behavior surveys), stated-preference surveys, and vehicle weight surveys.

Data gathered in the primary surveys are supplemented by secondary data surveys to build out the context and development patterns of the case in question. This category of survey is called secondary-data surveys, which include road inventory and reconnaissance surveys.

Road inventory surveys are conducted to assess the physical conditions of the road network in the area being analyzed. The aim is to identify infrastructural and capacity issues (for example, bottlenecks) and also to make assessments of the latent capacity of the network for informing future development and planning processes.

Road inventory surveys are designed to shed light on the following elements:

- Existing road hierarchy
- Geometrics and cross sectional elements of the roads and intersections

- Used and spare capacity levels, level of service (LOS), and bottleneck zones
- Street infrastructure (for example, lighting, signage, street markings, and guard rails)
- A rudimentary analysis of the existing problems, potentials, and possible constraints in designing and executing traffic management plans

Traffic Flow Surveys

Traffic flow surveys are conducted to get an estimate of the number of vehicles classified by type of vehicle on a given stretch of road at a given point in time. Typically, they are conducted round the clock using smart closed-circuit television (CCTV) for an average day. Technology advancement has made it possible to obtain counting/classification and spot speed estimation as a one-batch process using cameras fitted along the major road networks. Survey data is typically processed to give an estimate of the annual average daily (AADT), hourly (AAHF) or peak hour (PHF) flows, traffic composition, and directional split.

Speed Surveys

Speed surveys or spot speed surveys provide instantaneous speeds of vehicles at the recording site. These are typically used in accident analyses and to assess both the need and impact of various traffic management measures. A few of these measures include speed limits, signal settings, road markings, speed-change lanes, no passing zones, traffic signs, and pedestrian crossings.

Travel-Time and Delay Surveys

Unlike spot speed surveys, travel-time and delay surveys are designed to provide information about speeds over a stretch of road or an entire route. The total travel time contains the journey time and the travel-time delay (that is, the difference between the actual travel time and the travel time measured under non-congested traffic conditions). The primary aims of measuring journey speed, travel time, and delay time over road-network sections are to identify the causes and locations of traffic congestion, measure the before-and-after impacts of road and traffic management improvements, provide inputs for transport planning/trip assignment/route diversion models, and facilitate the economic analysis of alternative transport improvement proposals.

Origin-Destination Surveys

Origin-destination (OD) surveys are designed to extract information on the traffic flows between the designated zones in an area. OD matrices are the building blocks of any transport demand modeling endeavour and are of paramount importance. These matrices can be further broken down to be made suitable for meso- or microsimulation purposes. OD matrices are typically created separately for different transport modes, thus usually giving three sets of OD matrices—for cars, heavy vehicles, and buses.

Intersection-Turning-Movement Surveys

Intersection-turning-movement surveys are conducted to analyze the traffic flow (including pedestrian flow) conditions for major intersections. The primary aim of the survey is to extract flow and directional split on the different arms of the intersection along with the existing delay and conflict characteristics. The results from such surveys provide input for microsimulation of the critical intersections, the results of which are used to prepare both long-term geometric improvement plans and short-term traffic management plans.

Parking-Use Surveys

Parking-use surveys, accumulation surveys, and concentration surveys are undertaken to derive an estimate of the utilization level of the public parking lots, roadside parking, designated office or special space parking, and other parking types. The occupancy data give an idea about the demand and supply characteristics, hourly variations, and the possible impacts of planned projects in the future. It is essential that survey areas and time slots (in case a 12-hour survey is not possible) are clearly defined and earmarked to gather accurate data on the accumulation levels.

Parking use surveys are also essential in making mobility management plans, which aim to shift work-related mobility patterns from cars to public-transport usage.

Environmental-Impact Surveys

Environmental-impact surveys include both noise impact and air quality surveys. The unprecedented growth of motor vehicle traffic has been one of the major causes of growing noise and air pollution in cities. Noise impact surveys and air quality surveys

Traffic surveys also include parking-use surveys in public parking lots, such as this parking structure in downtown Santa Monica, California. Determining the number of parking visitors over a designated period of time can help in planning future projects.

are undertaken to keep a record of the level of pollution and to monitor the level contingent on various factors. Some of these factors include impact analysis of new programs, seasonal variations, possible solutions for ameliorating pollution, quantifying health effects, and others. Most of data is collected through advanced automated tolls and results are analyzed in software programs such as Soundplan for air pollution calculation and AutoCAD extensions for noise pollution analysis.

User Surveys

User surveys include public-transport-user surveys, cyclist surveys, and pedestrian surveys. The objective of this kind of survey is to elicit information from the end users regarding their needs, problems, and issues, and to gauge their reactions to existing or planned policies. The heavy dominance of quantitative data collection and techniques has come under severe critique in the last two decades, which has necessitated a wider use of such surveys.

Qualitative data is now considered vital to supplement the data collected from quantitative surveys. We can trace an almost linear development from the 1950s and 1960s, with a growing interest in designing for the car, to a people-centered emphasis

on improved living conditions in the 2000s. This evolving perspective can simultaneously be traced in a shift from traffic models to a needs/accessibility-based analysis. This is manifested by modifications taking place in areas governing the core paradigm, definitions and measurement, modeling and analysis, project evaluation, and a wider acceptance and usage of user surveys.

Operators Surveys

Operators surveys are conducted to extract details related to the operation of vehicles, for example, trip characteristics in terms of OD, modal composition, operational characteristics in terms of route of operation, vehicle utilization, passenger occupancy, operating cost and revenue, and reaction to the existing policies and programs. With an increasing focus on reducing car usage and boosting public transport utilization, such surveys provide vital inputs for bettering the existing public transport supply.

Travel Behavior Surveys

Travel behavior surveys include household, socioeconomic, and travel behavior surveys. Most of the developed countries have an established protocol for running countrywide travel behavior surveys. These surveys are comprised of three major sections: socioeconomic data, access to modes and related usage data, and details of trips undertaken. The data collection format for trips varies from country to country, ranging from weekly trip diaries to daily trip diaries. The inputs from these surveys form the basis of national-, regional-, and local-level transport modeling exercises.

The following points enumerate the classic approach followed in conducting travel behavior surveys:

- Designing of draft questionnaires
- Deciding on the mode of conducting such surveys, such as phone based, Internet based, or face-to-face interview
- Appointing and training of researchers or selection of a market survey agency
- Conducting pilot surveys
- Revising the questionnaire in light of inputs gathered from the pilot survey
- Conducting the main survey
- Coding, cleansing, and checking the data
- Analyzing the data

Stated-Preference Surveys

Although revealed-preference surveys are the most popular in traffic analysis, stated-preference surveys can be used to ascertain respondents' preferences for a given hypothetical set of transport options. The options are typically descriptions of transport situations or contexts constructed by the researcher, and, by their nature, stated-preference surveys require purpose-designed and targeted surveys for collection of relevant data.

Vehicle Weight Surveys

Vehicle mass data are critical to the structural design and management of highways and bridges and are used regularly in transport planning and economic studies. Vehicle weight surveys assist in charting seasonal pavement load restrictions, which ensure optimal performance and durability of highways.

Secondary Data Surveys

The primary traffic surveys provide information on the existing traffic characteristics and, in some cases, gauge the possible effects of proposed plans and projects. The secondary surveys, on the other hand, contextualize the findings from the primary surveys through proving vital inputs like land use characteristics; demographic trends; history and culture of the place, heritage sites to be conserved; accident data and accident-prone links and junctions; other planned urban or transport projects, policies; and funding outlays, among others.

Traffic Variables

The study of human movement serves as a prime example of how mathematics can be used to understand almost all aspects of our lives. From an algebraic standpoint, a variable is an element that must be taken into account to solve an equation; this is true in both simple pre-algebra equations or complex models constructed to predict human behavior.

Within the realm of transportation studies, traffic variables are used as part of complex models, which are used to predict the flow and other aspects of human movement. Thus, traffic variables are those elements that are taken into consideration to predict the movement of people. Almost anything even tangentially involved with transportation can be considered a variable, and these variables can be simple (such as speed) or complex and dynamic (such as those involved in commuting or traffic jams). In addition to automotive traffic, traffic models and variables can be used to understand airplanes, trains, pedestrians, buses, and personal automobiles.

The Mathematics of Human Movement

Humans are complicated creatures. Thus, the mathematics of the social sciences can be as complex, or perhaps more complex, as the mathematics of the natural sciences. Scientists studying commuter patterns use traffic variables as part of their traffic-flow models in order to achieve goals as diverse as easing congestion during rush hours, determining where a new stop light may be needed, and predicting the impact of a new convention center on congestion in a downtown metropolitan area.

Traffic variables are quantifiable elements that the developers of traffic models are able to take into account in their efforts to predict the collective human behavior that is the movement of traffic. When used in predictive models, the following traffic variables can be used: the distance between

cars in a given track of roadway, vehicle occupancy, population density in a given area, average weather patterns in the region studied, the density traffic must reach before creating a traffic jam (also known as jam density), the frequency of traffic jams, the average speed of a set of vehicles, the cumulative vehicle arrival function over space and time, the average speed of traffic when there are no constraints on movement (also known as free-flow speed), the speed at which deaths tend to increase, driver behavior, and fatality statistics based on car year, make, and model of vehicle.

Traffic modeling is performed in an effort to predict in a consistent way how individuals will move in a given area in a consistent way. Once transportation analysts compile data that could be used as traffic variables, they may then develop traffic models. Modeling is utilized to both improve existing systems (for example, streets, rail lines, and sidewalks) and plan new systems or elements that may interact with systems (for example, a new building or park).

Case Study of a Traffic Variable: Speed Limit

Vehicle speed is one of the most intuitive and easily studied traffic variables. Maximum and minimum speed limits have the effect of putting most vehicles within a certain speed range. This remains true even if many vehicles travel slightly above the speed limit. For example, if the speed limit were 65 miles per hour (mph) and the minimum speed were 60 mph on Interstate 71 outside Cleveland, Ohio, we could reasonably expect the average vehicle to be traveling somewhere between 60 and 75 mph. Thus, in this example, variation has been minimized and the traffic variable of vehicle speed is able to be integrated into predictive travel models.

The variable of vehicle speed can be used to predict many outcomes. Among these outcomes are the likelihood of accidents and the severity of regional pollution. Studies by the American Automobile Association (AAA) have shown that the risk of severe injury or death to pedestrians in collisions between vehicles and pedestrians dramatically increases as a vehicle's speed increases.

According to AAA, collisions between pedestrians and vehicles have about a 10 percent chance of fatality if the vehicle is traveling at 15 mph, but, as one would expect, the chance of pedestrian fatality increases as speed increases. At 23 mph, there is a 25 percent chance of pedestrian fatality.

The chance of pedestrian fatality dramatically increases as vehicle speed goes beyond the typical residential speed limit of 35 mph. At 50 mph, the chance of pedestrian death is 75 percent; and when a vehicle traveling at 58 mph strikes a pedestrian, the chance of pedestrian death is 90 percent.

By studying this traffic variable of speed, AAA was able to establish a clear relationship between vehicle speed and the probability of pedestrian death in collisions between vehicles and pedestrians. These results could then be used to justify lowering speed limits in residential areas or to persuade drivers to abide by already existing limits. The traffic variable of speed can also be used as a predictor of pollution. Studies have shown that increases in speed limits may result in a corresponding increase in air pollution. This was shown by comparing air pollution levels in metropolitan areas in Spain.

Atmospheric scientists compared air pollution in cities that decreased speed limits to 80 kilometers per hour (just under 50 mph) with those that did not decrease their speed limits. The study showed that those areas in which speed limits were lowered experienced nearly 11 percent decreases in air pollution levels. In this way, scientists were able to use the traffic variable of vehicle speed to predict air pollution. Results of this study may be used to both encourage drivers to abide by lowered speed limits on an individual basis and/or encourage additional cities to lower their speed limits.

Train Stations, Economics of

Historic and abandoned railway stations, or train stations, are being identified increasingly by private and public developers for reuse and redesign projects. Rail transportation and travel has changed markedly since the birth of the railways. These changes include predominantly operating technologies and systems, and user demands and expectations. These influences have resulted in the abandonments of many original railway stations and associated building, because of the unsuitability of stations in light of technological and social progress, as well as capacity and behavioral changes and the competition from a vast road transport network and highway development. In the United Kingdom, the number of disused railway stations totals 1,825 and is rising.

The golden age of railways and the train stations that once served lines now closed, or that have been replaced by larger, more modern and efficiently designed stations, evoke a fond and emotional nostalgia within many countries, including India, the United Kingdom, and the United States. Railway stations in the United States were once edifices of community pride, representing connections to a wider world beyond town limits, and they were celebrated. Many of these buildings, designed and constructed during and after the Industrial Revolution, display a vast array of unique architectural features and components reflecting local styles of

building and local materials. Indeed, leading architects, engineers, and contractors of the day were attracted by the fame, prestige, and money involved in railway building design and construction. This has resulted in often diverse building styles, ranging from gothic to neoclassical, Moorish to art deco, and Victorian to traditional. Many of these historic railway stations, therefore, are still recognized for their architectural merit and industrial heritage.

Some are identified as important buildings for protection and preservation by such heritage organizations as the Secretary of State for England and Wales, the World Heritage Committee, and the National Register of Historic Places (NRHP) in the United States. In fact, the NRHP emerged from the historic preservation movement triggered in the 1960s by the demolition of New York's original Pennsylvania Station.

To be considered for the NRHP, a structure must exhibit age, integrity, and significance. Owners of such designated properties can take advantage of tax benefits and funding opportunities. To provide property owners with a financial incentive to rehabilitate their historical structures, tax incentives for the preservation of historic structures exist at federal, state, and local levels.

Federal, state, and local grants for urban revitalization and local bonds proceeds—along with charitable foundations, private companies, community and interest groups, philanthropists, and private individuals—are among the funding sources that have contributed to the renovation of train stations. Although these historic buildings may have become a surplus for modern railway operational requirements, the reuse, revitalization, and renovation of unused railway stations provides communities with facilities for purposes other than those originally intended.

Repurposing Old Railway Stations

In the 2009 PennDesign report on planning for America's emerging high-speed rail system, prepared for high-level officials in the Department of Transportation and Federal Railroad Administration, one of the central recommendations was the reuse of historic train stations as part of the proposed American High Speed Rail (HSR) network.

The report stated that while "new stations will be needed in some cities, the renovation and reuse of America's historic train stations should be a central

tenet of the American HSR project that will help foster community pride and renew interest in the rail transportation.” However, where train stations are no longer needed for their primary function, with good design and imagination, historic railway stations can be transformed for a variety of uses.

Examples of these uses include but are not limited to museums, shopping malls, hotels, restaurants, markets, and residences.

The Gare d’Orsay in Paris, France was saved from demolition in the 1970s by the French government giving it preservation status and converting it to what is today the Musée d’Orsay. In the United States, the Cincinnati Union Terminal, designed by New York architects Alfred Fellheimer and Stewart Wagner and dedicated in 1933, is now repurposed as the Cincinnati (Ohio) Museum Center, which houses three museums within over 500,000 square feet. Similarly, in Kansas City, Missouri, there is an ongoing project to convert the French Renaissance central rail station into a science museum.

The Estação in Curitiba, in Brazil, was built in 1883 for the Curitiba to Paranaguá line. It now boasts a sprawling mall, 10 cinemas, and four museums. A steam locomotive remains permanently stationed in the mall as a reminder of the building’s past use.

Nashville’s Romanesque Union Station, opened in 1900, was constructed of locally quarried limestone, Tennessee pink marble, carved hardwoods, stained-glass windows, and wrought iron. Today, the center-city landmark is the site of a luxury hotel. At the other end of the Nashville, Chattanooga and St. Louis Railway line is another Romanesque Union Station in St. Louis, Missouri. Originally opened in 1894 as the largest single-level passenger rail terminal in the world, the station closed in 1978, but the building now houses a shopping mall and the Hyatt Regency Hotel.

On the other end of the luxury spectrum is the colorful, rustic, and environmentally friendly hostel La Vieja Estación in Puente del Inca in Aconcagua, Argentina, which used to be the station for the Transandine rail line operating through the Andes Mountains between Chile and Argentina. It has been turned into a hostel for travelers visiting the nearby Aconcagua National Park. El Galpón in Buenos Aires, Argentina, is a marketplace for fresh, local, and organic produce and products.

The Deptford Project in London is a restored part of the station that escaped an earlier partial

demolition and is now used for restaurant facilities. In the Meon Valley in Hampshire, England, many of the now closed branch line stations are being bought by private individuals to repurpose as private accommodations or guest houses.

Train Stations Revived as Destinations

The reuse of train stations has gone beyond single-use repurposing. In Denver, Colorado, the \$900 million Union Station redevelopment is following the example of many mixed-use renovation projects that have helped revive urban centers throughout the United States. The mixed-use Union Station development, scheduled to open in summer 2014, will include the historic 1881 station building and almost 20 acres of surrounding land. In addition to hotel, retail, office, and residential development, a central feature of the project will be its multimodal transportation hub, which will bring together Amtrak regional trains, several commuter rail lines, a 1,100-foot-long underground bus depot, and a free shuttle to nearby stations of the light rail transit system.

Train stations also provide municipal office space. In Pueblo, Colorado, and Collierville, Tennessee, the old stations house the city administration. In Louisville, Kentucky, the reuse of the station was recognized by the Department of Transportation and the National Endowment for the Arts with a Design for Transportation Award for the transformation of its station into offices for the Transit Authority of River City. The repurposing involved a high level of restoration, including cleaning the stained glass and ceramic tiles and restoring the red oak staircase and paneled walls. This project also demonstrated that the perception that reuse and renovation of these buildings is disproportionately expensive in comparison to a new building is flawed. The total cost of renovation was calculated to be just three-quarters of that of a new facility.

Renovation and restoration projects involving train stations are diverse and towns and cities are capitalizing on the old buildings, not just for their intrinsic value but also for the boost they provide their communities. Historic railway stations and their associated buildings are places that are deeply rooted in the American experience, and this emotional connection leads to the pressure, desire, and availability of support from the public in protecting and repurposing them.

Not only does the reuse of historic railway stations preserve and improve the building and its architecture—as well as its heritage—for the future but it also offers economic and social benefits, which include the following:

- Construction costs are usually significantly less than new buildings because the structure and the site are already in existence, although challenges associated with new types of land use and proposed activity may arise.
- Jobs are created, not only in the renovation work, but also through the much longer-term revitalization of the surrounding area.
- Rail station developments can have wider economic development and rejuvenation effects on infrastructure and services within the adjacent area. With the transformation of old railway stations follow associated mixed office, shopping, and residential uses.
- The location of these stations is often in downtown and central areas, providing ease of access for local inhabitants, commuters, and travelers.

Nonetheless, repurposing old railway stations is a major undertaking. To preserve the rich architecture and history of these buildings requires all new electrical and mechanical systems, which must be located strategically to reduce visual intrusion on the historical aesthetics. Also, specific historic designations on these buildings may prohibit particular renovation work or structural alterations, thus precluding certain types of uses.

Conclusion

Abandoned and unused railway stations are attractive buildings for reuse. They are often located close to or on existing infrastructure networks and are proximate to services and customers. Repurposing these buildings is increasingly attractive, not only because of the grants and tax incentives that may be available, but also because of the architectural merit of these buildings. Further, they represent an attractive option for developers facing difficulties associated with new development on greenfields.

The popularity and passionate feelings toward old station buildings are beginning to resonate

beyond Western countries, too. For example, South Korea is one country where the benefits of revitalizing these buildings for other useful purposes is being recognized.

Trains

Trains are a mode of transport operating on exclusive tracks typically traveling over longer distances than subway or elevated railways. Most train routes were built in the 19th century principally to provide freight transportation, which in many countries is still the case. When passenger trains began operating between freight trains to serve adjacent cities and suburban areas between them, developers

quickly saw the opportunity to build residential areas along those routes to cater to commuters.

Train Target Market

The present-day passenger train market typically targets people with personal automobiles who commute by rail into the nearby central business district (CBD), either because the journey is too long to drive in an appropriate frame of time, because roads are congested, parking in the CBD is limited, or they have made a choice in favor of a less environmentally damaging transport mode.

In the United States, the average commute time is about 40 minutes. Train commuters help raise this average by their long commute times, often over an hour. The London (United Kingdom) train commuter market stretches from Peterborough in the north to

Southampton in the south, from Folkstone in the east to Bristol in the west, up to 120 miles (190 kilometers) distant from the center of London. New York also has a large train commuter catchment, with the Long Island market stretching about 100 miles away as one of the earliest and continuously operational.

Trains also target longer-distance journeys between cities hundreds of miles apart. In the United States, the National Railroad Passenger Corporation/Amtrak serves more than 500 destinations in 46 states, the District of Columbia, and three Canadian provinces. Amtrak's busiest route is the Northeast Corridor that connects Boston, Massachusetts, with Washington, D.C., and New York City with both; it also serves Philadelphia, Pennsylvania, and Baltimore, Maryland, and several smaller cities and regional hubs. Approximately 260 million intercity

A passenger train like this one in San Mateo, California, can consist of several locomotives and coaches and may use double-decker cars to carry more passengers per train. In the United States, more than 2,200 trains traverse some portion of Amtrak's busiest route, the Northeast Corridor between Washington, D.C., and Boston, Massachusetts, every day. Amtrak's entire network serves 46 states and more than 500 destinations, carrying as many as 260 million intercity and commuter rail passengers per year.

and commuter rail passengers rely on Amtrak annually, and more than 2,200 trains operate over some portion of the Washington–Boston route every day.

With congested airspace and unpredictable weather affecting short-haul airline flights along this heavily traveled corridor, Amtrak carries triple the number of passengers between Washington, D.C., and New York City as the airline industry, and more riders than all commercial airlines combined between Boston and New York.

Whether passengers are commuters or intercity travelers, the main attraction of trains is their fast operating speed made possible by stations widely spaced and a high maximum running speed. Because the distribution of trip length is primarily short journeys, trains are aiming at a small proportion of all trips, but carry a large percentage of those trips.

Function of Railways

The exclusive use of the rail right-of-way offers a number of important advantages, not least of which is a high operating speed in an uncongested (that is, exclusive travel) environment. The second advantage is that trains operate from and between exclusive stations, where value-added functions for passenger trips can be offered, such as park-and-ride lots that make multimodal travel with cars and trains more convenient.

The ability to collect trainloads of passengers at a station improves operating economics, leading to full (or nearly full) trains for much of the length of the line. On some systems, express trains are offered end to end for a market, with stopping trains calling at a limited number of intermediate stations.

With fewer stations than a subway, train lines often have bigger stations and longer trains to provide high-capacity flows, with fewer trains in use. Longer trains also allow in-transit passenger services, such as meals and refreshments, a value-added service and a further attraction for train use.

New Railways

With existing rights-of-way and an infrastructure of rail routes, a railway has the potential to be enhanced in economical ways. However, where a new railway is proposed to be built, the costs increase by at least one order of magnitude. Among other additional obstacles, they may face community opposition if the land for a new right-of-way is purchased compulsorily.

In order to justify this much bigger capital cost, the operating benefits must be substantial. Ideally, passenger numbers and revenue should more than cover operating costs, leaving a surplus to retire some of the capital debt. If this ideal is not possible, the project falls back on cost-benefit analysis, where non-revenue aspects—such as congestion reduction, pollution mitigation and other reductions in environmental impact, passenger (that is, worker) time savings, more mobility options for people without personal cars (often low-income and/or disabled), and potential reductions in automobile traffic crash deaths and injuries—are added to financial considerations.

Unfortunately, the value of these non-revenue items is more subjective than dollars-and-cents return on investment (ROI). In many UK cost-benefit transport analyses, passenger travel time savings is the most highly considered among the benefits. Often, these savings are merely a few minutes. Moreover, where journey times are themselves variable, planners and agencies ask whether travelers will choose a non-auto mode based on minutes saved and, if they do, whether that time is put to any useful use.

One location option for new rail line rights-of-way could be the median of existing freeways, which could be both more economical and less contentious. Bus use of high-occupancy vehicle (HOV-lanes) on freeways rarely attracts more than 10 percent of existing commuters, therefore not providing a significant increase in overall usage.

On the other hand, the equivalent lane space in the median for rail use would provide a significant increase in capacity, with research showing trains often nearly double the flow of passengers versus personal cars at peak times. Furthermore, rail lines are proven to get commuters out of their cars, not just reducing car vehicle flows and peak congestion, but also leading to an overall speeding up of journeys, not to mention environmental benefits.

Whether a new rail line uses a new right-of-way or a freeway median, the choice of station location is critical to the success of the line. Such success is often determined by the park-and-ride capacity of the lots of stations along the route.

Freeway Relief

Virtually all major cities suffer from the same traffic characteristics, namely, a very high morning

and evening peak, causing congestion, with excessive pollution emission, and spare road capacity at other times. In terms of land use, private automobile trips are the least efficient way to move around large built-up areas, not only because of the land required for the roads and junctions, but also for parking at the destination of the commute trip. This is particularly acute when the CBD is a major work destination; maintaining an efficient density of economic activity is difficult when auto parking has to be accommodated, even in multilevel structures or basement parking under high-rise buildings.

A train track takes up as much space as a freeway lane but can carry 10 times the passenger flow. When planning new rail lines, therefore, a freeway alignment can be an excellent option for the following reasons: following proven high demand, making better use of the land, increasing the passenger capacity of the freeway, reducing the congestion and pollution from car traffic, and being socially acceptable.

There are examples of freeways being taken out of service, usually as a result of some kind of emergency. One of these was the Embarcadero Freeway in San Francisco, which was a double-deck structure. A major earthquake in 1989 collapsed part of the upper deck onto the lower, killing a number of drivers. By the time the city was in a position to do something, traffic in the area had adjusted to the reduced capacity and traffic continued to flow without gridlock. The freeway was demolished in 1991 and adjacent property prices rose by over 100 percent. The space was reused for residences, a parkway, and a streetcar line, greatly improving the local environment and turning what had been an undesirable part of the city into an attractive area.

Obviously, the introduction of a new rail line with more capacity than the freeway along which it is located increases the options of the future use of the land occupied by the freeway.

Modal Split

The key to planning, funding, and improving or building rail lines is that car commuters will switch to rail. Rail opponents always claim that their city is unique and the car commuters are wedded to the steering wheel. Even if large scale market research is undertaken, people are very poor at predicting changes of their behavior in the absence of a real alternative choice. Two options are then available to rail planners; faith—or looking at other cities with improved

or new rail lines and extrapolating that experience to their unique home city. Faith is an unpredictable to determine the way people will react to a new development, and there are many examples, often demolished, of developments that failed to attract users and could not be justified economically.

Modeling mode split is now an exact science, based upon the probability of one mode of transport being chosen over another. For large groups (for example, a suburban neighborhood), this probability translates into the proportion of all trips made by auto that will be attracted to rail. The key to that modeling is the accurate representation of the characteristics of each mode, as viewed by users, in terms of travel time, reliability, and cost.

Historically, data to calibrate modal-split models were collected manually and transferred to computer for analysis. Today, cell phone origin-destination (OD) data, based on departure and arrival zones, offers orders of magnitude more data, and potentially outputs of a much higher level of accuracy than is possible from traditional manual sample surveys.

The advantage of modeling mode choice is that it allows sensitivity analyses to be undertaken to examine the outcomes of “what if” scenarios. What if gas jumped to \$20 a gallon, what if toxic auto air pollution worsened and large areas were made car-free as a public health measure? These different scenarios are quick to analyze and allow the planners to focus on one or two likely scenarios to see how best the railway can serve the community.

This focusing should include the location of rail stations, not only to maximize the catchment of the target car-commuting households, but also to best serve the most frequently used destinations. This also allows an assessment of the optimum location and size for park-and-ride stations. Such an assessment will include capturing inbound trips from outside the metropolitan area and the most attractive combination of parking and rail charges.

Part of the modal-split assessment will be the comfort and convenience of interchange to rail. The Skokie Swift (Yellow) Line in northern Chicago is a practical example of starting a rail line with a modest expenditure, and as increasing auto commute trips were attracted, the trains and stations have been enhanced. Right from the start, Skokie Swift offered 34 miles per hour (mph) transit, faster than was possible by driving parallel roads.

Almost every city can find an example where a low-cost starter rail line can be enhanced incrementally as traffic increases, so that there is at least a positive cost-benefit return, even if there is not a hard financial return. Either way, this makes better use of public money.

Sustainability

Sustainability has two major strands: environmental and financial. All too often environmentalists believe the rail system will be environmentally benign, making things no worse and ideally beneficial by reducing emission of toxic pollution and carbon dioxide, as well as reducing traffic noise.

Within this argument, rail systems, whether powered electrically or by diesel engines, will produce pollution. With electric power, the pollution is remote from the urban area and could be produced from renewable sources (for example, hydroelectricity). The amount of pollution released in the construction of power generation and a new rail line is trivial compared to car emissions. Even operational pollution is relatively small because of the high overall efficiency of the electricity cycle, with about 30 percent of input energy being converted to useful work in carrying passengers on trains, which themselves are an order of magnitude

less energy-dependent than rubber tires with much higher rolling resistance.

For diesel trains, this equation is not so clear-cut. First, diesel engines are heavy polluters, especially of particulate matter. Second, the pollution is released along the rail corridor and at stations, therefore exposing passengers and residents. Third, no matter how carefully diesel trains are fueled, there will be leakages from trains in motion and at fueling points that can pollute groundwater. Offset against this, there are now many programs to produce diesel fuel from biomass, and, therefore, to be more sustainable. Nevertheless, the energy efficiency of the diesel engine cycle is only about 20 percent.

Development Stimulus

There is little doubt that an improved or new rail line can be a major stimulant to urban development. This results from both push and pull factors. The “push” factors center around the improved accessibility that areas with rail services enjoy and the increased capacity for moving people economically and quickly. The “pull” relates to the increase in land values resulting from improved accessibility to “central places.” Such increases in land values make the intensification of development density financially viable and practical. More people can

India has one of the largest rail networks in the world but does not have high-speed rail lines capable of supporting speeds of 200 kilometers per hour, or km/h (124 miles per hour [mph]) or more. Proposals for high-speed corridors operating at 300 km/h (186 mph) on elevated tracks have not yet been implemented. The fastest train in India is the Bhopal Shatabdi, with a top speed of 160 km/h (99 mph).

live/work/shop in a given area because extra transport capacity is available and acceptable.

The pioneering study of this effect was made after the Yonge Street subway opened in Toronto in 1954. This showed a consolidation of small building lots into larger, and then the replacement of low-rise by high-rise buildings clustered around subway stations. This is exactly what central-place theory predicts. Further, this intensification of land use and the resulting rise in property values was an order of magnitude larger than the public investment in constructing the subway. Subsequent extensions of the Toronto subway have replicated this.

Studies in Boston, Los Angeles, New York, Philadelphia, Portland, San Diego, the San Francisco Bay Area, and Washington, D.C., showed positive correlations between rail transit opening or improvement and the value of adjacent commercial and residential property. This has also been replicated in cities in other countries.

Various proposals have been made for “value recapture” taxes, where the public gets back part of the rise in property values to cover some of the public investment in rail that made it possible. Normal urban property taxes are a crude and not very effective basis for recapturing public investment, because they depend on the regular revaluing of property—not usually an election winner. The other direct way in which public investment can be recaptured is by the rail authority buying land at station sites, which can be used for building the rail line and the stations. The remaining spare land can then be developed, as well as air rights for residential, commercial, or retail activities, depending on the station location.

Tramways

There is little difference, historically, between tramways in Europe and streetcar systems in North America. They both followed similar development paths and heavily influenced one another. Initially, tramways were built to make horse traction more efficient. On the dirt roads of the 19th century, two horses could pull a maximum of 20 passengers in a bus, but 50 in a tram running on smooth rails. At that time, tramways provided transport for middle-income people and the poor walked everywhere.

What changed the characteristics of the tramway was the advent of electrification, which allowed bigger trams to carry 100 passengers, still with a crew of two, and to operate faster services, reducing unit operating costs and, therefore, the fare charged.

Probably the biggest difference between Europe and North America is that most tramways were taken into public ownership in Europe at the beginning of the 20th century, while in North America many streetcar systems remained privately owned and operated until the middle of the century. In Europe, many tramways were operated as part of the social policy of city councils to enable poor people to travel, and the availability of tramways enabled city-center slum dwellings to be replaced by suburban public housing. Tramways being run as departments of the city council usually meant that no financial depreciation was made, and maintenance was often neglected to the point where total replacement was required.

At this point, tramways were often closed and replaced by cheaper buses. The argument was that

roads were already being maintained, so they might as well be used by buses.

This experience was common in the United Kingdom (UK), Denmark, France, Ireland, Italy, Spain, and Sweden. Unfortunately, the tram passengers did not all switch to replacement buses, and, in most places, bus patronage was less than 70 percent of what it was on the clanking and slow trams.

Popularity Versus Bus Transit

In the developed countries of the Organisation for Economic Co-operation and Development (OECD), the main means of personal travel is now the private motor car. Public transit, of which tramways are part, is a minor carrier, with notable exceptions.

The city of Freiburg in Germany began an environmentally sustainable policy for transport in 1990. Since then, car use has declined to less than one-third (32 percent) of all trips, while transit has increased to 20 percent, which compares with an average of 3 percent for cities in the United States with a similar population.

How have such increases in transit in Europe been achieved? The answer lies in auto commuters' perception of transit. In most European cities, buses are the only form of transit, and buses are not viewed as an acceptable alternative to private car use. In contrast, car commuters are more willing to switch trips to rail, and tramways are perceived to be a rail service.

Germany, in particular, retained trams long after other European countries had scrapped theirs. Today, there are 85 tramways operating in Germany, nearly as many as the rest of Europe put together. German cities are both expanding their tramway networks and improving services, so that many lines are hybrids of classic tramways and modern light rail systems. Freiburg is a good example of the impact of modest but consistent investments in improving and extending tramways leading to an attraction away from car trips.

Nottingham in the UK reopened its (first) tramline in 2004 and is now constructing a second line. Since 2004, transit use has increased to 20 percent of all city trips. Both tram lines serve park-and-ride stations in the suburbs, part of the city's policy to divert car trips to transit. The experience of attracting trips from cars to trams has been repeated for all the UK and French tramways built since 1985. Typically, between 25 percent and 35 percent of tramway

passengers left their car at home or at a park-and-ride station.

Operational Requirements

The ideal rail system for an urban area might be considered a subway, or metro. However, the high cost of construction limits the number of lines that can be built. Tramways can provide 90 percent of the benefit of subways at 10 percent of the capital costs, because routes are normally built in existing city streets.

To maximize the utility of an investment in tramways, passengers must feel they will travel more quickly in a tram than by road. To ensure that experience, tramcars need traffic management that favors them, such as the provision of exclusive lanes and priority at traffic signals. These will also reduce power consumption by reducing the stops and starts tram must make (aside from stops for passengers to embark or exit).

Tram stops are located where patronage can be generated, such as residential areas and park-and-ride stations, or attracted, such as hospitals, universities, shopping centers, and the central business district (CBD). This has been the model for all European tramways built since 1985 and often results in tramways with small networks carrying more passengers than buses.

Although construction of a new tram line costs more than putting buses onto the streets, their operating costs can be covered by fares, which is not always the case with other modes. For example, in Nantes, France, within two years of opening tram line One, transit ridership had increased by 30 percent, with trams carrying 18 percent of all transit trips.

By 2007, three tram lines in Nantes were carrying 20 percent more passengers than the original bus network. As importantly, although tram operating costs are 40 percent higher than buses per mile run, trams generate over 12 percent more revenue than operating costs, whereas buses barely cover half their operating costs. So trams, in fact, are subsidizing bus services.

Impact on Urban Development

Like rail services, tramways have a positive impact on urban development. A good case study is Sheffield, England, where an out-of-town U.S.-style shopping mall called Meadowhall with 10,000 parking spaces was opened in 1990. Quickly, this

decimated city-center shopping, leaving closed and boarded-up shops in the CBD.

In 1994, a tramway opened between Meadowhall and the CBD. The Meadowhall tram stop was part of an intermodal interchange with a regional rail station, and the local bus service station also located there. Soon, a reverse in traffic flow was observed, with shoppers driving to Meadowhall, doing some shopping, and then getting on a tram to the CBD. That has resulted in the rebirth of the CBD with small, independent, and specialist shops, restaurants, and other facilities.

Modal Share

Trams get people out of cars, either all the way or for some trips. This modal switch explains why cities with trams enjoy a higher proportion of trips by transit than those that are dependent on buses. The policy implications of this are large, because many cities have erroneously operated under the belief that busways provide tramway services at minimal costs. The premise, though, is that busways will lure enough people from their cars to justify the service.

The first major busway development was in 1967 when Runcorn New Town was built in the United Kingdom, with all development clustered around a busway designed as a figure-eight network with the town center at the cross. The plan was based on the assumption that 50 percent of all trips in Runcorn would be by bus.

Even though the freeway system was built outside the town, where car trips would take longer than bus trips, the highest modal share the buses ever achieved, in the mid-1980s, was 15 percent. Today, it is only about 5 percent. When doing their analysis, planners in Runcorn failed to identify that people with cars have the ability to make local travel choices; if the alternative they are given is a bus, the car is preferred in the majority of cases. Therefore, if cities are serious about getting people to make fewer trips by car, one way to achieve this is by building and developing a tramway network.

Interchanges

Tramways are rather modest infrastructure developments, carrying potentially fewer passengers than a subway but more than a bus route. Interchanges, then, will be commensurate with that capacity. The most basic interchange is a pedestrian- and perhaps

cyclist-access tram stop that in most countries must be fully accessible for passengers with physical disabilities, requiring a platform, signage, and shelter.

The next level will be interchange with park-and-ride (P+R). As an example of the scale, the Nottingham tramway has five P+R stops, from which 5,000 trips per day are generated, 20 percent of total daily ridership. So a P+R stop will be scaled differently from a normal tram stop.

The most complex interchanges will be with other tram lines and rail lines. These may be at grade, and, if so, it should be possible to arrange the interchange at the same platform or perhaps a cross-platform interchange. If grade separation is involved, a convenient route between platforms on different levels will be needed, including elevators for those with mobility impairments or in wheelchairs. Larger numbers of passengers will also be involved in interchanging, so wider platforms and access ways are required to make movements between modes smooth and safe.

Network Structure and Service Quality

Historically, tramways were structured with routes serving many passengers to many destinations, but sharing sections of a common network. Today, the structure is usually fewer passengers to fewer routes, but run at a high frequency (for example, under five minutes), with convenient and coordinated interchanges. This allows passengers to enjoy “many-to-many” routing options for the heaviest flows, with a high-frequency walk-up-and-go service.

Service is more than the mechanics of having trams turning up on time. It also includes presentation. Tram stops that are clean and maintained will be more attractive than ones with litter and peeling paint. The same applies to the trams. They need to be externally cleaned every day and regularly repainted externally to give a showroom finish.

A simple route network is easy to operate and, therefore, easier in theory to maintain a highly reliable service. When people have the alternative of a car, a tramway that is not operating with clockwork reliability will soon lose its passengers.

Transit Centers

Historically, discussions involving "mass transit" might involve air travel, heavy rail, light rail, buses, bicycling, walking, and carpooling, but each of these modes of transportation—and the locations where one was able to begin a journey using it—were considered separately and independently. For a variety of reasons, planning and policy considerations have coalesced to create new interest in transit centers serving multiple purposes and combining several modes of transportation. These centers are becoming an exciting way to expand economic opportunities while also encouraging sustainable behavior.

While some municipalities have chosen to integrate their light rail systems with pedestrian urban malls, others have elected to downplay this connection and instead to utilize abandoned railroad rights-of-way in an effort to cut costs. As a result, transit centers represent both a bold new way of combining multiple modes of transportation in an effort to revitalize neighborhoods and to drive economic development or an endeavor to minimize terminal costs and the havoc construction and rebuilding often cause.

Background

Beginning in the 19th century, greater thought and planning began to be placed into the design and location of terminus sites for travel by rail, ship, carriage, or other modes of travel. For the better part of a century, civic pride and commercial success resulted in ever larger railway stations, bus depots, and other edifices to modern transportation.

After World War II, however, the growth in popularity of travel by automobile and airplane had an effect on centers for other modes of travel. For much of the latter half of the 20th century, mass transit, while not ignored, was not the focus of most urban developers or transit planners. As the 21st century dawned, however, a new generation began to explore how intermodal transit centers could both support sustainable practices and drive economic development.

Cities and other urban centers represent an accumulation of resources and a concentration of activity. Both of these are represented and supported by the transportation systems present in the area. In many ways, transportation systems offer the most opportunities where the greatest gathering of resources and activities takes place. This, in turn, can cause problems.

Many transportation terminals—such as ports, railway stations, bus depots, and airports—are located within urban areas. As a result, traffic congestion, parking shortages, longer commutes, environmental degradation, health risks, polluting land usage, and logistical delays often occur in or near these places. As policy makers and planners have examined these events, many have determined that automobile dependence is a primary cause of many of these. As a result, ways to diminish reliance on the automobile have been reviewed and considered as one way of reducing these problems.

Automobile travel became popular for a variety of reasons. Some of these are individual, such as convenience and consumer choice. Others, however, have been societal, such as the decision to underprice the cost of automobile travel through subsidies to roads and freeways. Communities that want to decrease their reliance on the automobile may take a variety of steps in that direction, including dissuading drivers through speed bumps or parking restrictions, prohibiting motor vehicles at certain times of the day, or enacting tolls for use of the roads.

Transit centers have come to be viewed as an additional way in which congestion, pollution, and gridlock can be addressed. Featuring more than one mode of transportation, transit centers attempt to combine the benefits of more solitary modes of traveling—such as bicycling, driving, or walking—with a mass transit experience.

The combined experience eliminates some of the disadvantages of each, because taking an automobile two miles to catch a 25-mile commute by train makes the process more convenient than either automobile or rail alone. While location plays a large role in an individual's decision whether to use intermodal transportation, planning and policy decisions can also greatly affect the attractiveness of a given choice.

Urban or suburban locations located near major transit centers, whether railway stations, subway stops, bus routes, or the like, benefit in increased land values as a result of this proximity. Mass transit systems, however, require a certain degree of population density in order to be successful. Certain past decisions on the part of transit organizations, such as charging a flat fee for travel, made the fare structure simpler, but also worked to discourage shorter trips for which mass transit is ideal. For intermodal transit to work effectively, all aspects of a system must be considered and changed if necessary.

Encouraging Intermodal Transportation

Appropriately designed and strategically placed transit centers are an ideal way of encouraging intermodal transportation. Transit centers are helpful in combining two or more modes of transportation in ways that combine the strengths of various commuting choices for travelers while also offsetting their weaknesses.

In many urban areas, the decision to develop transit centers that encourage intermodal transportation is to reduce the reliance on automobile travel while simultaneously encouraging the use of mass transit, bicycling, jogging, or walking. As progress, not perfection, is the goal of transit centers, accepting a certain level of dependence upon the automobile is acceptable, as is the idea of offering incentives to make mass transit more popular.

Many policy makers have accepted that most travel has always been intermodal. The trick is to convince commuters that it is their benefit to combine one type of rapid transit, be it rail or bus, with

other options, such as bicycling, driving, walking, or the like.

In an effort to encourage rail travel, for example, many policy makers combine incentive parking, sometimes known as park-and-ride, with bus or rail systems in an effort to get commuters to take mass transit. Incentive parking permits commuters the convenience of driving their automobiles on the initial and final legs of their commutes, while enjoying the benefits of mass transit for much of the journey.

Incentive parking, which is often offered at no or low cost, is seen as luring those who might not otherwise take public transit into the system. Critics of incentive parking, however, suggest that such schemes do little to reduce on-road traffic over time but do create entitlement programs that chiefly benefit the well-to-do. Some communities have experimented with bike-and-ride programs that encourage commuters to ride a bicycle to a transit center and then to take mass transit to reach a more distant destination. Bike parking takes up considerably less space than that for automobiles, yet such a system is impractical in many areas because of inclement weather during much of the year.

Other communities have attempted to funnel riders onto rail or high-speed buses through offering convenient feeder buses that transport commuters the last few miles at either end of a trip. Feeder buses work best when they are scheduled to arrive shortly before or after the arrival of the next leg of the commute and do so in a timely manner. When successful, feeder buses inspire rider loyalty, while also increasing revenues for the transportation system. In some areas, one company, such as a rail provider, will pay another, usually a bus operator, to provide this service because it can greatly improve the profitability of both carriers.

Some enticements to encourage those who might not otherwise consider using mass transit are quite inexpensive for carriers. For example, many metropolitan bus lines, especially those in warmer climates, now provide free bicycle carriers on the front of their vehicles. Such devices encourage those who would not otherwise consider taking a bus to their destination but will if permitted to bring the bicycle with them.

A similar situation involves trains or ferries that permit drivers to drive their automobiles onto the larger vehicle. Such an arrangement permits the

travelers to enjoy the use of their automobile once at their final destination and encourages use of lower-mileage routes, which saves fossil fuel and reduces road congestion. Again, some criticize such endeavors because they assist those who would otherwise be able to afford other options.

Intermodal Passenger Transit Centers

Transit centers work best when a variety of modes of transportation are available to commuters. For that reason, intermodal passenger transit centers appear most frequently in large urban areas that offer a variety of forms of transportation, such as heavy rail, light rail, bus, and others. Although highly popular, for example, fewer than 200 communities globally have subway systems in place. This scarcity is in part because of the great investment initially required to build such a system, as well as the necessity that there exist adequate ridership to make such an investment practical. In those large urban areas that have developed transit centers, use has often been made of extant terminals that operated previously as part of a preexisting transit system.

The Chicago Transit Authority (CTA) is one of the largest transportation providers globally, operating surface rail, a subway, and buses. It has transformed its Jefferson Park Station into the Jefferson Park Transit Center to take advantage of a variety of transit options available to commuters. In addition to the CTA's own Blue Line rail service, the Jefferson Park Transit Center offers stops for the Union Pacific/Northwest commuter rail offered by Metra (the commuter rail agency serving Cook, DuPage, Will, Lake, Kane, and McHenry counties in the Chicago area), CTA buses, and Pace (the suburban service) buses, as well as providing parking spaces for automobiles and bicycles. As a result, the Jefferson Park Transit Center serves over 2 million passengers a year, with ridership growing by over 5 percent per year.

In addition to providing access to a variety of transportation offerings, some transit centers are designed to include amenities and services that will attract potential riders, such as coffee shops, retail venues, bars, and other services that attract the busy commuter. While such offerings in and of themselves will seldom be enough to affect a user's decision to use a transit center regularly, they do work to assist those with other obligations to feel comfortable about their transportation choices. Ultimately,

transit centers work if the connections between lines are speedy, convenient, and within proximity of the traveler's home or destination. Amenities and services, however, can help inspire loyalty.

Transit Corridor Planning

Signed into law on July 6, 2012, by President Barack Obama, the federal Moving Ahead for Progress in the 21st Century (MAP-21) Act sets requirements for transit corridor planning in the United States.

In Section 5309, funds are authorized for Fixed Guideway Capital Investment Grants, also called New Starts, which apply to rail transit in all forms (for example, regional rail, commuter rail, light rail, streetcars, single-rail transport (that is, monorails), and transit that operates on a separate right-of-way exclusively for public transportation (for example, bus rapid transit and ferry systems). The program provides grants for new and expanded rail, bus rapid transit, and ferry systems that reflect local priorities to improve transportation options in key transit corridors.

This program defines a new category of eligible projects, known as core capacity projects, which

In 2012, the New York City subway completed over 1.65 billion passenger trips. The MAP-21 Act authorizes funds for new and expanded transit systems in other U.S. cities to help increase mobility, reduce congestion, and improve air quality.

expand capacity by at least 10 percent in existing fixed guideway transit corridors that are at or above capacity today, or are expected to be at or above capacity within five years. The program also includes provisions for streamlining aspects of the New Starts process to increase efficiency and reduce the time required to meet critical milestones.

The Federal Transit Administration (FTA) discretionary New Starts program is the federal government's primary financial resource for supporting locally planned, implemented, and operated transit guideway capital investments. From heavy to light rail, from commuter rail to bus rapid transit systems, these public transit investments have improved the mobility of millions of Americans, helped reduce congestion and improve air quality in the areas they serve, and fostered the development of viable, safer, and more livable communities.

Fixed Guideway Capital Investment Grants

State and local government agencies, including transit agencies, are eligible for this FTA program. MAP-21 modified the Capital Investment Program by expanding the eligibility to Core Capacity Improvement projects and streamlining the project development process. New Starts projects are defined as projects with a total capital cost of \$250 million or greater or

that are seeking \$75 million or more in section 5309 funding. Eligible projects are new fixed guideway systems, such as rapid rail (heavy rail), commuter rail, light rail, hybrid rail, trolleybus (using overhead catenary), cable car, passenger ferries, and bus rapid transit, or an extension of any of these systems.

Small Starts projects are defined as projects with a total capital cost less than \$250 million and that are seeking less than \$75 million in section 5309 funding. Eligible purposes for the Small Starts program are those mentioned for the New Starts program, as well as corridor-based bus systems that do not operate on a separated right of way but include features that emulate the services provided by fixed guideway systems, including defined stations, traffic signal priority for public transit vehicles, and short headway bidirectional services for a substantial part of weekdays and weekend days.

MAP-21 also makes Core Capacity Improvement projects eligible for section 5309 funding. These are substantial corridor-based investments in existing fixed guideway systems that are at capacity today or will be in five years. A Core Capacity Improvement project must increase the capacity of the existing fixed guideway system in the transit corridor by at least 10 percent.

MAP-21 reduces the number of steps in the process for projects pursuing capital investment program funding. For New Starts and Core Capacity Improvement projects, the steps in the process consist of project development, engineering, and construction. For Small Starts projects, the steps in the process consist of project development and construction. Alternatives analysis no longer is required.

The FTA must evaluate and rate projects seeking section 5309 funding according to statutorily defined criteria at various steps in the process. The FTA is responsible for implementing changes under MAP-21 to improve the efficiency of the New Starts and Small Starts processes, and implementing the new Core Capacity Improvement process through rule-making and policy guidance, which will be developed through a notice and comment process.

Project Development Process

Under MAP-21, the new Project Development Process achieves the following:

- Eliminates the alternatives analysis requirement and instead relies on the

review of alternatives performed during the metropolitan planning and environmental review processes

- Creates the Project Development phase during which the environmental review is completed; project sponsors must complete this phase within two years or seek an extension from the FTA
- Reduces the number of FTA approval steps by consolidating Preliminary Engineering and Final Design into a single engineering step
- Requires the FTA to develop an expedited review process for determining the technical capacity of project sponsors to undertake the proposed project if they have recently and successfully completed at least one other new fixed guideway or core capacity project

Under New Starts, the Project Development phase requires a complete environmental review process, including developing and reviewing alternatives, selecting locally preferred alternatives (LPA), and adopting it into a fiscally constrained long-range transportation plan.

Under Small Projects, the Project Development phase entails the following:

- Complete environmental review process including developing and reviewing alternatives, selecting LPA, and adopting it into fiscally constrained long-range transportation plan
- Gain commitments for all non-5309 funding
- Complete sufficient engineering and design

There are two key phases in transit corridor planning in the project development process for projects seeking New Starts funding: Alternatives Analysis (AA) and Preliminary Engineering (PE).

Alternatives Analysis

An AA is a transit corridor planning study in which one or more of the alternatives under study is, or includes, a fixed guideway facility. It has as its basis the New Starts planning provisions contained in federal legislation. AA is synonymous with multimodal corridor planning, consistent with the principles

of both the Major Investment Study (MIS) process practiced in many areas around the country and the Draft Environmental Impact Statement (DEIS) required by the National Environmental Policy Act of 1969 (NEPA). Regardless of what the study is called, its intent is the same: to identify and compare the costs, benefits, and impacts of a range of transportation alternatives as a means of providing local decision makers with the information necessary to implement the most appropriate transportation solutions in priority transit corridors.

AA can be viewed as a bridge between systems planning at a metropolitan scale, which identifies regional travel patterns and transit corridors in need of improvements, and Preliminary Engineering, where a project's design is refined sufficiently to incorporate the avoidance, minimization, and mitigations necessary to complete the environmental process. AA is the process designed to facilitate the reaching of a broad consensus on exactly what type of improvement(s) best meet locally defined goals and objectives for a specified transit corridor.

Because it involves specialized technical analyses and an evaluation of transportation alternatives that have varied effects on the surrounding community, the AA is necessarily a collaborative process. The AA study typically involves local transportation planning agencies (including the metropolitan planning organization) and service providers, local governments, state and federal resource agencies, potential funding partners, and the general public, through a formal citizen participation process.

There are a multitude of ways that an AA can be coordinated with the environmental review required by NEPA. NEPA itself mandates that the EIS reflect an analysis of all reasonable alternatives, so the careful coordination of the AAA and NEPA review is essential to the efficiency of the study and to public and interagency understanding of the process.

Various coordination methods have been used, such as "incorporation by reference" to carry the AA results into a NEPA document or use of a first-tier or programmatic EIS as an AA. While the decision to conduct the AA either within or outside the NEPA process is an important milestone, which should be agreed upon as early as possible within the study process, the FTA emphasizes that the appropriate level of analysis is a function of the complexity of the transit corridor and its transportation needs, not of the regulatory framework. The level of analysis

should be commensurate with the planning decision at hand; that is, the analysis of every issue should be carried just far enough to make an intelligent selection of a preferred transportation design concept and scope from the alternatives available.

Preliminary Engineering

During the Preliminary Engineering phase of project development, local project sponsors refine the design of the LPA to the extent necessary to complete the NEPA process, taking into consideration all reasonable design options. Preliminary Engineering results in estimates of project costs, benefits, and impacts for which there is a much higher degree of confidence. The proposed project's New Starts criteria are similarly refined in the Preliminary Engineering phase of project development. In addition, project management plans should be finalized, products of the PE effort that demonstrate the technical capability of the project sponsor to advance further in development should be substantially completed, and commitments of local funding sources should be firmed up (if not previously committed).

Preliminary Engineering for a major capital investment project is considered complete when the FTA declares in the environmental Record of Decision (ROD) or Finding of No Significant Impact (FONSI) that the NEPA process has been completed; when the project scope, capital costs estimates, and financial plan are finalized; and when the project sponsor has adequately demonstrated to FTA its technical capability to advance the project into final design and construction. Proposed New Starts and Small Starts projects are evaluated and rated according to criteria set forth in the law. The statutory project justification criteria include mobility improvements, economic development effects, environmental benefits, congestion relief, land use, and cost-effectiveness. The statute also requires the FTA to examine the following when evaluating and rating local financial commitment: availability of reasonable contingency amounts; availability of stable and dependable capital and operating funding sources; and availability of local resources to recapitalize, maintain, and operate the overall existing and proposed public transportation system without requiring a reduction in existing services.

MAP-21 has changed the technical approach for transit-corridor planning in America. The elimination of AA has streamlined the project development

process. Transit corridor planning is more adaptive or flexible, but it also must be constrained by project justification criteria for New Starts and Small Starts by FTA.

Transit Cost Allocation Models

Transit cost allocation is part of the larger process of cost analysis for a transit system. The first step in cost analysis is cost determination, the process of gathering information about the total cost of operating a transit system and of any individual service

components that will be analyzed separately. The cost allocation process follows cost determination and involves distributing or allocating costs to specific service components, such as the total operating costs for a group of vehicles that may need to be apportioned to individual vehicles.

Cost allocation models are often used to calculate the expected costs or savings from changes in service provision, or to compare different ways of providing a service. However, not all transit cost allocation models are the same, with one important difference being the type of costs included in different models. For this reason, it is vital to understand the details of the particular model used in an analysis, particularly if the purpose of the analysis is to compare costs between, for instance, public or private provision of services. Cost allocation models are also used to determine how much of the costs of a shared transit system should be paid by the different entities involved.

The Three-Variable Unit Cost Model

Three kinds of costs are considered in transit cost allocation models:

1. Variable costs are those directly linked with providing vehicle transportation, such as fuel, vehicle maintenance, and driver salaries; if transit services are increased or decreased, there would be a change in variable costs, as well.
2. Semi-fixed costs are costs influenced by the services provided, but with a less direct link to changes in those services, such as the cost of rolling stock.
3. Fixed costs are long-term costs that are not affected by marginal changes in transit service levels, such as administrative costs and building maintenance.

Most transit cost allocation analyses use the three-variable-unit cost model, with the three variables in this model being vehicle hours (VH), vehicle miles (VM), and vehicles (V). This model assumes that the total cost of operation is directly related to the number of vehicles in the system, the number of miles that they travel, and the hours of service provided, so that the total expenses of the system can be apportioned to these three variables. This model can also be used to calculate the cost of providing a

particular route or service, as well as the total costs of the transit system, and can be used to calculate either annual costs or costs for a shorter period.

Although the cost of operating any transit system includes fixed, semi-fixed, and variable costs, not all cost allocation models include all three variables, or the full range of costs within each variable.

In a fully allocated model, variable, semi-fixed, and at least some fixed costs are included, although capital costs are usually excluded. In a partially allocated model, variable costs and at least some semi-fixed costs are included. Fully allocated models are often used to compare different transit systems or different modes of transit, while partially allocated models are often used to forecast the changes in costs associated with proposed marginal changes to services.

The choice of which model to use and which costs to include in each category influences the results of the analysis, so it is vital to know in detail which model was used and how it was applied when interpreting any analysis.

Sometimes the inclusion or exclusion of expenses is based on practical factors, such as funding sources. For example, capital costs for a city transit system may come from state and federal funds, and thus not be included in the cost allocation model, which is concerned primarily with the funds acquired from local subsidies and fare collection. Particularly when estimating the influence of proposed service changes, the true quality of a model can only be evaluated after the fact—a good model accurately predicts changes in costs, while a poor model does not.

Alternative Approaches and Models

Researchers have described cost allocation models as one of four approaches to cost modeling. The other three are (1) causal-factor models compute total costs as the sum of the resources used (driver's time, fuel, parts, etc.) multiplied by the unit cost of each resource; (2) regression models use a sample of data to estimate coefficients for variables that influence costs, such as distance traveled, number of vehicles, fleet age, and drivers' salaries, and use the resulting equation to calculate expected total costs with different levels of the variables; and (3) temporal variation models account for the variable costs of providing services at different times of the day, in particular, at peak versus nonpeak travel periods.

Several different cost allocation models can be used. The simplest is the average cost allocation

model; it allocates all the costs of a system to a single output, such as the total distance traveled by transit vehicles, the number of vehicles in operation, or the total hours during which services was provided.

The three-variable unit cost model discussed above represents a step-up in sophistication, because it is one of the models that allocates costs to several operating outputs (for example, vehicle miles, vehicle hours, and total vehicles). This type of model can be described as a fully cost allocated model, without making the partially/fully allocated distinction that is observed in the previous discussion. The most complex models are differentiative fully cost allocated models in which distinctions are made among costs on the basis of temporal variation, activities, or inputs.

Allocation of Operating Costs

Cost allocation is used in another sense with regard to public transit: it refers to the ways the costs of a transit system are allocated among different geographically or politically defined areas. For instance, a bus system might serve both a city and parts of the surrounding county; because the city and county have separate budgets, both need to pay for part of the system's expenses, and cost allocation is used to decide how much of the transit system's budget will be provided by the city and how much by the county. The most common cost allocation methods in this context are to assign costs by route, or according to population, passengers, services hours, or service miles. A combination of these systems may also be used, making the allocation potentially more accurate but also less transparent.

In the route assignment system, the entities involved come to an agreement about which one benefits most by a particular route, and that entity provides funding for the route. In the city-county example, some routes entirely within the city might be seen as providing most benefits to residents of the city and would be paid for by city government, while routes linking the county to the city might be seen as providing most benefits to county residents and thus be paid for by the county government.

A population-based system is based on the number of people served by the system and/or the density of population in the area served. A passenger-based system allocates costs based on the number of riders from the different areas. Service-hour and

service-mile systems allocate costs based on the hours of service or miles of service the transit system provides to each entity.

Criticisms

Some critics charge that the cost allocation models used to answer questions about the cost of a transit trip or the variation in subsidy on different routes or among different classes of passengers mistakenly treat the costs of transit service as uniform, when in fact costs vary widely according to factors such as trip length, time of day, and type of service. They contrast the sophistication of cost models used by airlines and shipping companies with those used in many public transit systems, and charge that the lack of detailed information about the costs of providing different services makes it difficult to set effective policies or manage the transit budget wisely.

Brian Taylor and his colleagues have created a model using data from the Los Angeles Metropolitan Transit Authority, incorporating marginal variations in capital costs, vehicle capacity, and time of day, and found significant cost variation by mode—lower costs for incremental service increases, and higher costs for both peak and off-peak service.

Transit Demographics

Public transportation services are provided in every state in the United States in some form or fashion. Most urbanized areas operate fixed-route public transit services and many rural areas have fixed or demand-response transit services. In addition, many public transportation services are provided for the transportation of the elderly and people with disabilities.

The demographic characteristics of transit riders thus reflect the demographic characteristics of the population of the geographic area served by the provider. Public transit providers use publicly available data to understand the characteristics of the population in their service areas and may periodically survey their passengers to understand the demographics of transit riders in order to enhance or adjust existing services to meet their customers' needs. Publicly available data on demographic characteristics of transit users include the U.S. Census Bureau's American Community Survey (ACS), the Federal Highway Administration's National Household Travel Survey (NHTS), and the American Public Transportation Association's (APTA) onboard surveys.

The characteristics of transit riders vary depending on the form of transit (for example, bus, subway, or train), the trip purposes (for example, work, leisure, or school), and trip frequency. In order to understand transit demographics, one must first define what universe will be measured. Nationally, according to onboard surveys conducted by the APTA, the majority of riders on public transit (59 percent) rode

transit to get to and from work in 2007. Another 11 percent rode public transit in order to get to and from school, 9 percent of riders used public transit to get to dining or shopping, 7 percent for recreational/social reasons, 3 percent to reach medical services, and 12 percent for other reasons.

Because the majority of public transit users ride transit to get to and from work, and because census data is used to help plan for transit services and allocate resources, the ACS reports the modes of transportation used by workers on the journey-to-work (or work commute). The NHTS provides statistics on people in households who used public transportation during a specified travel day and the data can be sorted by trip purpose, including the work commute.

Both the ACS and the NHTS are surveys of a randomly selected sample of the population in households. In contrast, the APTA survey collected demographic information of riders who were riding on public transit vehicles throughout the country.

Characteristics of Public Transit Riders

Nationally, the population using public transportation is racially and ethnically diverse, but over-represented by racial and ethnic minorities, primarily because of differences in socioeconomic resources.

Although the majority of the U.S. population in the early 21st century is non-Hispanic white, representing 68.1 percent of the civilian workforce, only 39.9 percent of workers commuting to work between 2006 and 2010 were non-Hispanic white, according to the ACS. Non-Hispanic blacks were more likely than any other group to ride public transportation and accounted for 23.9 percent of work commuters using public transportation.

Two of the fastest-growing groups in the United States, Hispanics and Asian and Pacific Islanders accounted for 24.1 percent and 5.6 percent, respectively, of public transit riders on the journey to work. The APTA survey of riders found similar statistics when surveying passengers riding on public transit systems in 2007. Continued growth in the minority population, and in particular in the Hispanic and Asian and Pacific Islander population, will mean that public transit riders will become increasingly Hispanic and Asian and less non-Hispanic white.

Public transportation plays an important role in providing transportation for those who do not have access to a personal automobile or other forms of

transportation, and, as a result, it is often associated with people who have lower incomes. However, public transportation can also provide transportation to those who have access to vehicles but wish to avoid road congestion; reduce transportation expenditures for gas, maintenance, and parking; or choose to ride transit for environmental and other reasons.

As more people locate to and live in major urban areas, where public transportation is widely available, more people will ride public transportation. In fact, according to the NHTS, 52.7 percent of commuters using public transportation of some form in 2009 had incomes of \$50,000 or more.

The work commute remains the single most cited purpose for taking public transit. Thus, it is not surprising that most transit users are in the primary working ages of 16 to 64. In fact, the majority of transit riders on the work commute (57.4 percent) were between the ages of 30 and 64 in 2009, according to NHTS, while only 8.4 percent were 65 years or older and 34.2 percent were younger than age 30.

In the early part of the 21st century, the majority of riders on public transportation were women, accounting for 52 percent of all public transportation riders, according to APTA onboard surveys, and 50.8 percent of riders on the work commute, according to the NHTS.

Characteristics by Mode Type

The demographic characteristics of riders vary by the type of transit system used. According to the NHTS, 36.3 percent of bus riders on the work commute were non-Hispanic white in 2009, compared to 48.8 percent of riders on rails. African Americans accounted for 27.6 percent of bus riders and 20.6 percent of rail riders. Hispanics accounted for 26.8 percent of bus riders, but only 14.5 percent of rail riders, likely a result of the geographical distribution of rail systems relative to concentrations of Hispanic people. Asians and Pacific Islanders accounted for 6 percent of bus and 10.5 percent of rail riders, respectively.

The majority of bus riders on the work trip are women (55.4 percent), although they are the minority, at only 44.3 percent, of riders on subways and commuter rail. Riders on rail are older, on average, than those riding public buses. Only 18 percent of commuters riding some form of rail (subway, commuter rail, trolley, etc.) were under the age of 30, compared to 29.9 percent of public bus riders.

Commuters on a subway platform in Toronto, Canada, in 2011. The demographic characteristics of transit riders in the United States have been found to vary by the type of transit system used. For example, the majority of bus riders on the work trip are women (55.4 percent), although they are the minority, at only 44.3 percent, of riders on subways and commuter rail.

Those riding public subways and trains are more likely to be riding public transit system as a matter of choice than those riding public buses, who tend to ride buses because they do not have access to a personal vehicle or other forms of transportation. Public rail riders are more likely to be in the prime earning ages, and the income distribution of public transit riders on rail transit are skewed toward higher income ranges. Whereas 61.7 percent of bus commuters had incomes of less than \$50,000 in 2009 and 20.8 percent had incomes less than \$15,000, only 29.1 percent of commuters riding commuter rail, subways, and other rail systems had incomes of \$50,000 or less.

Immigrants

Immigration has been an important component in the growth of the United States throughout its history. Many larger urban areas serve as gateway cities: places where new immigrants arrive and live

with or around other immigrants who can assist the new immigrant in navigating their way through a new culture. Public transportation can play an important role in helping immigrants who may have no other means of transportation to travel to work, school, and other activities. However, language barriers and unfamiliar ways of navigating public transit systems may hinder immigrants from using public transit systems.

To remedy these issues for immigrant people, public transportation agencies must understand the different immigrant populations present in their service areas and develop strategies to eliminate language and other cultural barriers. In time, immigrants assimilate into the culture and adopt the transportation use patterns of nonimmigrants. Transit agencies, therefore, need to not only find ways to eliminate barriers to ridership among new immigrants but also find ways to retain immigrants as riders of public transit.

Transit Dependence

Transit dependence (also known as transit captivity) refers to individuals or markets that rely on transit for most or all of their travel needs. This is usually discussed in contrast to “choice” users who have access to a private vehicle but choose to use transit. An individual is considered transit dependent if he or she has no driver’s license or lives in a household without a private vehicle.

Transit captivity is also discussed at the market or neighborhood level, where demographic factors such as age, disability, or low income are identified as indicators for transit dependence. In the United States, about 30 percent of the population 5 years of age and older is considered transit dependent.

Transit captivity is an important concept in transit planning and modeling, because captive markets account for around 70 percent of transit trips in the United States. They are seen by transit agencies as a secure market because it is assumed that captive users who have no other transportation options will always use transit. Although this may be the case in the short term, if the captive market is neglected, the long-term effect could be users changing their behavior, such as by purchasing an automobile, changing home location, or forgoing trips.

Transit agencies tend to focus on attracting “choice,” or discretionary, riders, because it is assumed that those users will only select transit if it is superior to the car in regard to cost, time, and/or convenience. Discretionary users are more likely to change their transit use in response to changes in fare, travel time, and reliability than captive users.

The proportion of transit-dependent travelers using a system depends on the transit mode and network coverage. Captive riders tend to dominate in low-quality, infrequent, and dispersed networks typified by local bus systems. In contrast, high-frequency, radial commuter-oriented networks, typified by light and heavy rail, tend to attract a larger proportion of choice riders. This is because

efficient, radial rail networks are more likely to be a competitive alternative to private motor vehicle travel and therefore attract choice riders. In contrast, local bus systems are usually uncompetitive compared to private cars and are more likely to be used by transit-dependent populations that have few travel options.

In much of the United States, transit-dependent households face a transportation environment particularly unsuited to their situation. Rapid decentralization of housing and jobs has dispersed travel destinations in a way that puts many locations out of reach of public transportation. Transit-dependent households generally have poorer access to jobs, education, and other important destinations than households with access to a car.

In American cities, transit-dependent households can access only 40 percent of metropolitan jobs within 90 minutes of travel on transit. Low-income job seekers are more likely to find work if they have access to a car than if they are reliant on public transport. Studies in the United Kingdom have found that many job seekers, especially young adults, cite a lack of personal transport as a significant barrier to finding work. People without a car are much more likely to miss medical appointments, have difficulty accessing grocery stores, and may forgo social activities because of their lack of transport options.

Equity and Environmental Justice

Transit dependence often plays an explicit or implicit role in discussions about transit and social equity. This is because transit dependence is closely associated with socioeconomic disadvantage, low income, and social marginalization. Household car ownership is closely tied to household income; some 60 percent of American households in the lowest income category do not have access to a vehicle, as compared to only 8 percent of American households overall. Ethnic minorities are also more likely to live in households without access to a car and are more likely to take public transport to work.

As mentioned above, transit-dependent populations tend to be over-represented in low-quality local bus systems and under-represented in efficient rail networks. This can result in a tension between the two objectives of transit systems, which are to provide an economically efficient system that

reduces road congestion and environmental pollution, and to provide a basic level of access for all persons, especially the transit dependent.

The former objective is best served by commuter-oriented radial transit systems, often at the neglect of dispersed transit-dependent markets with diverse travel needs. The latter objective is served by lower-patronage transit networks with broad geographic coverage and low service frequency. In an attempt to improve the economic efficiency of transit systems, some cities have resorted to paying for improvements to commuter rail systems (which primarily benefit white-collar, middle-income workers) through increasing fares and cutting back local services (which disadvantages low-income, transit-dependent communities).

In the United States (and to a lesser extent the United Kingdom), the social equity implications of these decisions are generally played out under the banner of the environmental justice movement. The origins of the movement date back to the 1960s, stemming from Title VI of the 1964 Civil Rights Act, which states that “no person in the U.S. shall, on the ground of race, color or national origin” be excluded from any federally funded program or activity.

Although originally applied primarily to land use issues, such as zoning and the placement of landfills, more recently the term has been applied to transportation issues and supported by more executive and federal orders through the 1990s. Under legislation, any change to a transport system is meant to consider whether programs will have a disproportionately adverse impact on minority and low-income populations.

For example, if a new light rail system will be funded by increasing bus fares, an environmental justice assessment should be undertaken. If it is found that high-income workers will primarily benefit from the light rail system, whereas low-income (transit-dependent) workers will be disadvantaged by the increased bus fares, then mitigation strategies must be put in place to reduce the imbalance (for example, by increasing bus levels). Environmental justice issues have resulted in at least one successful class action against a transit operator.

Choosing Transit Dependence?

Much of the discussion of transit dependence presumes people are forced into dependence as a

result of circumstances beyond their control. This is especially true in the United States, where most cities and rural areas are highly automobile-oriented and transit networks are sparse.

However, it is worth noting that some people choose to be dependent on transit, that is, they are able to purchase and drive a private vehicle but choose not to. These individuals tend to live in cities with dense transit networks and restrictions on private vehicle use, such as high parking charges or congestion pricing. There is increasing evidence that people of Generation Y (or millennials) are more likely to live in accessible urban areas, are driving less than previous generations, and are more likely to delay or forgo acquiring a driver's license.

Furthermore, there is some evidence that the most common measure of transit dependence—no household vehicles—is becoming less valid with the rise of car-sharing companies (called car clubs in the UK). In many cities, households that may have traditionally been locked into transit dependence because of the expense of owning and running a car can now use a car sharing service for some trips at relatively low cost.

It is unlikely that transit dependence will ever be fully divorced from issues of socioeconomic disadvantage. Yet, emerging transportation options raise interesting questions about how transit dependence will be conceptualized and addressed into the future.

Transit Fares

Transit fares are fees that are charged to passengers for use of a public transportation system. Broadly defined, public transportation systems include any passenger service that is available to the general public. The discussion presented here focuses on transit fares in the context of urban mass transit and commuter rail systems. In this discussion, the terms *boarding* and *unlinked trip* refer to the same thing: a ride that is taken on a single transit vehicle.

In contrast, a linked trip covers the entire journey between the traveler's origin and destination, whether the journey involves a single boarding or multiple boardings. In a linked trip with multiple boardings, the first boarding is often called the initial boarding and each subsequent boarding is called a transfer. Most transit operators offer a heavily discounted rate or no charge for transfers. The term *fare system*, which is commonly used but somewhat vague, refers to all components of fare collection, including the creation of a fare structure or the determination of fare prices and policies, the types of fare products or media that are offered, and the collection of fares.

Fare System Objectives

The primary objective of most fare systems is to generate revenue that helps cover operator costs. The concurrent maximization of ridership is also desirable for many reasons. First, higher ridership suggests that a large number of individuals find the transit service to be a beneficial transportation option, an important achievement because the purpose of public transit is to provide mobility to the population. Second, high ridership facilitates progress toward other social goals, such as improving air quality, reducing road congestion, reducing parking facility needs, and improving accessibility.

Transit operators usually seek to balance revenue needs with ridership maximization, but fare systems typically do not generate enough revenue to cover all costs that are borne by the transit agency. The balance of costs is made up in part by subsidies.

When designing their fare systems, operators frequently target additional objectives. Transit agencies often offer an array of fare products to better meet the needs and preferences of their customers. Various fare collection technologies, such as stored value (magnetic stripe) cards, can make fare collection faster, less costly, and more reliable. Furthermore, agencies can construct policies that allow customers to transfer inexpensively, helping keep service affordable to customers when direct service between the origin and destination is not provided or is not preferred.

Fare Structures and Key Elements

To help achieve these objectives, each public transit agency establishes a system of fare pricing and related policies—called the fare structure—to which its riders must adhere. Fare structures can include a variety of schemes to determine how much fare to collect from each passenger. Flat fares are prices that do not vary by distance, time of day, or other dimensions. Variable or graduated fares, unlike flat fares, vary. Examples include the following:

- Distance-based fares vary depending on the length of the trip
- Zone-based fares are similar to distance-based fares, but use a simplified system in which nearby stations are typically grouped together (into a single zone)
- Peak/off-peak fares vary by the time of day or the day of the week
- Transfer policy determines the price of boarding additional vehicles (after the first boarding), and can include stipulations on when or where transfer rates may apply
- Discounted fares allow some categories of riders to ride for a reduced price (or for free)

While these elements are commonly observed across public transportation fare systems, an individual system usually uses only two or three of these elements.

Transit agencies typically use either flat fares or variable fares, although there are some examples (discussed later) of fare systems with elements of both. Transfer fares are relevant for systems with a flat-fare structure and in systems where fares vary by time of day or day of week. Transfer fares are not

used in systems that are entirely distance- or zone-based because the fare price in such systems depends on the length of the trip rather than the number of vehicles boarded. Practically all transit agencies offer discounted fares for some passengers, including seniors, riders with mobility impairments, or students. This is true regardless whether the overarching fare scheme is flat or variable. Agencies also typically offer multiple ways to pay for fares, such as a flat rate or an unlimited pass. Similarly, most agencies allow customers to pay with a variety of media, such as cash, stored-value cards, and smartcards.

Flat Fares

A flat fare is a fixed price that is charged to passengers each time they enter the system. The price may differ for population subgroups, but the basic mechanism is the same.

A key benefit of flat fares is that they are simple for riders to understand and remember. From the operator perspective, collection of flat fares is straightforward but generally requires more handling than passes. Flat fares and unlimited passes can be more simplistic than variable fares for operators to administer, although these differences are being reduced with advancements in smartcard technology.

Agencies generally offer several ways for customers to pay flat fares. The most basic method is cash. Tokens (coin-like slugs) were once popular, but their usage decreased when stored-value cards became common. The value that is held in stored-value cards can usually be replenished through ticket-vending machines at transit or retail locations. More advanced technologies, such as smartcards and contactless credit cards, are a variation that allows replenishment using an Internet-based account.

Transfer Fares

Transfer fares apply to the second or third (or subsequent) boarding of linked trips that involve multiple boardings. Transfer fares are usually much lower than the initial boarding rate; sometimes they are free. Until recently, operators typically provided a paper ticket to the passenger upon the first boarding to use for boarding subsequent vehicles. As the usage of cash and tokens declines, most transit systems now use magnetic-stripe (that is, stored-value) cards or other media to provide transfers.

Transfer policy historically has focused on facilitating travel between origins and destinations that

are not directly served by a single transit vehicle. Using this policy, operators can effectively price a trip requiring two or more boardings at a level that is the same or slightly higher than a one-vehicle ride. Therefore, while the burden of transferring from one vehicle to another may still discourage some customers from using transit, operators attempt to keep the total fare of such trips in line with one-seat fares so that fare prices do not create another impediment.

There are two transfer policies in common use today. One policy allows the riders to use the transfer fare to make transfers (usually up to two) en route to their destinations. In general, the transfer must be used within a specified time window. This policy prohibits or discourages riders from using the transfer rate for the return trip.

The other commonly used policy is similar, but riders are permitted to use the transfer rate for the return direction. The latter policy creates a flexible fare mechanism that can effectively be used by passengers as either a flat fare or something akin to a very-short-term unlimited pass.

Discounted Fares

Fare price discounts, where riders pay less than the full posted fare, are offered to riders who meet certain conditions. If the fare structure includes a flat fare, then the flat fare usually is the basis of comparison when evaluating the discount. Discounted fares are offered in most transit systems worldwide and can be classified based on the following:

- The fare instrument that is used and/or the amount of trip-making for which it is utilized
- Passenger characteristics
- The origin and/or destination of the trip
- The time of the day or day of the week (time-of-day discounts are discussed under variable pricing)
- Discounts based on fare instrument or frequency of use

Transit agencies frequently set different prices for fares paid in cash and fares paid using other media. Because of the high costs of dealing with cash, agencies may penalize the use of cash fares in comparison to other fare media, such as fare cards and transit passes. Regardless whether the cash

fare or the card fare is considered the “true” base fare, cash-paying riders often pay more than other passengers for each trip. Unlimited-ride passes allow riders to take as many rides as they want within a specified time frame. For example, a one-day pass permits the rider an unlimited number of rides in a single day. Pass prices usually provide a discount for frequent usage. As such, regular riders may essentially receive a small discount per trip compared to passengers paying a single-ride fare, and heavy users end up receiving more significant discounts. At the same time, pass holders who end up not using the transit system as much as they anticipated may overpay for those transit trips they do make.

Similarly, some agencies offer discounts to riders who purchase a set amount of rides or stored-fare value at one time. For example, a 20 percent discount may be provided when a 10-ride ticket is purchased. Alternatively, a discount may be offered when a minimum value threshold is met or exceeded; for example, a 10 percent discount may be offered when a stored-value card is replenished with at least \$20.

A number of transit agencies offer a special pass to university students (sometimes called a U-Pass), which is priced at a very low rate and covers a semester, quarter, or other term. In many but not all regions, the low cost of the pass is somewhat offset by the fact that all active students pay for the pass (often as part of their general student fees for each semester), regardless how much they use the transit system. This particular type of discount is partially related to the fare media, but is primarily related to passenger characteristics, since the pass is restricted to actively enrolled university or college students.

Discounts: Passenger Characteristics

In addition to providing fare discounts to university students, transit systems commonly offer reduced fares to children. In large urban areas, public transit serves as a substitute for school bus service and discounted fares are justified on that basis. High school and sometimes middle school students may have passes provided by the school district that further reduce the cost to the student.

Despite this policy background, school district revenues do not necessarily go to transit agencies to make up the difference in fares. Instead, state

legislatures historically have provided some general revenue for the purpose of making “whole” the transit agency, although this can be cut back during budget crises.

Charging lower fares for children making non-school trips is typically justified on social welfare grounds, that is, that public transit would be unaffordable for families with several children. Very young children typically ride for free.

In the United States, federal law requires agencies to charge seniors at least 50 percent less than the regular adult off-peak cash fare. Some agencies allow seniors, or some categories of seniors (for example, low-income seniors), to ride for free. One drawback of fare structures that delineate among multiple classes of passengers is that different fare media often are needed to account for their rides. This complicates the management and maintenance of the fare system. While low-income riders occasionally receive discounts from the transit agency directly, it is more common for outside social agencies to provide passes to their clients and not directly involve the transit agency.

Discounts: Origin and Destination of Travel

Discounts (or penalties) that are applied to specific origin and destination pairs of transit trips are conceptually similar to zone-based fares. Some typical examples of this fare policy are surcharges for trips going to or from a regional airport and free fares for trips made within downtown areas.

Airport surcharges are often justified on the grounds that the cost of the airport extension has to be paid for separately from the rest of the transit system. Surcharges can also help cover other airport transportation costs, including traffic handling and traveler information costs.

Free downtown fares, in contrast, are viewed as a way of promoting transit generally and specifically encouraging people to use transit for shopping and other business in the downtown core. They do not typically have a dramatic fiscal impact on the transit agency because few people would pay full fare for such short trips. Further, the fact that the free downtown service is available during the day may induce some people to take transit to work rather than driving (where the car might otherwise be needed for in-city trips). These free trips may be restricted to off-peak hours to reduce interference with commuter travel.

Variable Pricing

Variable fares generally are defined as fares that vary based on trip characteristics or service types. Variable pricing means that the cost of a transit trip depends on its characteristics. Fares may vary based on trip distance, the “zones” the passenger travels through, time period, travel time, or type of service. In the most complicated fare systems, a combination of characteristics (such as distance-based fares that vary by time of day) may be utilized.

Variable fares can benefit the transit system operation in several ways. For example, peak fares can shift travel to the off-peak or the peak-period shoulders, relieving crowding and improving travel-time reliability during the busiest transit hours and making more efficient use of off-peak service. Distance-based fares may help operators recoup costs more efficiently (and possibly more equitably) than flat fares. Higher prices for faster or higher-quality service can increase revenues using a market-based approach that is acceptable to the ridership population.

In comparison to flat fares, however, variable fares are relatively complex for passengers to navigate and for operators to administer. For example, if fares vary for peak and off-peak, then the number of flat fares can effectively double. When applied to unlimited pass products, the concept of fare variability becomes more complicated because it adds a restriction to a fare product that otherwise permits unlimited travel. Fare collection technology must be sophisticated enough to determine the correct fare and to do so reliably. Distance-based or zone-based fare collection can be expensive to integrate because of special capital requirements, such as installing exit barriers.

Service Quality

Differential pricing for various levels of speed and type of service are often used. For example, many systems charge a premium for rapid bus because it offers faster service than a local bus. Similarly, some systems charge different rates for rail and bus to account for their perceived differences in quality of service.

Fares Based on Distance or Travel Zones

In distance-based pricing systems, the amount of fare to be paid increases with the length of the trip. Depending on the operator, trip length is measured using track miles or Cartesian distance.

Infrastructure requirements typically include entrance and exit barriers or another form of operator monitoring to assess the distance traveled. Zone-based pricing is a simplified form of distance-based pricing where groups of stations are treated as a single unit (or zone) for purposes of fare pricing. Regions often use a small number of zones to maintain simplicity.

Distance-based or zone-based pricing is commonly used by commuter rail systems, where collecting these types of fares is relatively simple. The main reason for this is that because most commuter rail passengers are traveling between their homes and a downtown area, operators have enough time to collect fares and to determine the proper fare to charge the occasional passenger traveling to a destination other than downtown.

In contrast, distance-based or zone-based pricing is more difficult to design and administer—and, therefore, relatively uncommon—in urban mass transit systems, where travel patterns are more geographically dispersed and bus-to-rail transfers are common.

Fares Based on Time of Day of Travel

Many transit agencies charge different prices for peak and off-peak service. Common forms of time-of-day pricing include lower fares in the off-peak period and/or on the weekend (or a single weekend day). Peak periods tend to be defined as approximately 6 A.M. to 9 A.M. and 3 P.M. to 6 P.M., although this definition varies by agency. Lowering fare prices in the off-peak is justified by the fact that fare elasticity is higher in off-peak periods, meaning that a discount during these times will generate a larger percentage of new riders than during the peak periods.

Furthermore, transit vehicle utilization rates tend to be relatively low during the off-peak periods. From a policy perspective, this strategy helps attract riders to ride more during these underutilized periods. Depending on how the peak periods are defined, it might be possible to shift some transit riders away from the peak usage period to the off-peak, which also alleviates the need to purchase additional transit vehicles to be used only for peak demand.

Transit Fares, Elasticity of Demand of

Transit fares are a component of system management that can be adapted and tested at different levels, thus yielding an elasticity of demand experienced largely as changes in ridership levels. Demand can be measured in the number passenger boardings; total passenger miles provided; or, on a somewhat more sophisticated plane, mean revenue miles. Some studies have indicated that the regular passengers of a given transit service tend to be more sensitive to changes in fare price and in other variables of that service. In a sense, they become better informed over time.

They also build up a set of expectations beyond fare price; these involve factors such as trip time, seat availability, comfort level, effects of weather conditions, and experiences at different times of the day. Two non-fare factors that seem particularly potent are anything that has the effect of delivering reduced waiting time, and the availability of express services.

Extensive surveys of urban transit systems have attempted to determine the extent of these and other causal factors of fare elasticity. Generally, these surveys are weighted to de-emphasize

extraordinary ridership increases, such as those generated by special deep discount appeals to strictly defined demographic subsets (for example, university students).

It has been discovered in the aggregate that regular transit riders are indeed sensitive to fares. They tend to reward stable or declining fare levels with increased ridership—as much as 5 percent annually, or even more in some studies. Still, in practice, the effect of fares seems universally to place second to the effect of service expansion or contraction.

Among tertiary factors, it has also been noted that there are at least three fairly potent demand determinants that are out of the control of administrators to increase or decrease—but that seem to have considerable staying power. The three quite often cited are the income level of riders and potential riders, the cultural tastes and preferences of such riders, and the prices these riders pay locally for related goods or services.

Case studies conducted in transit markets as diverse as Victoria, British Columbia, in Canada; Santiago, Chile; London, England; the West Bank of Palestine; and in the United States, Houston, Texas; Los Angeles and San Diego, California; Portland, Oregon; and Seattle, Washington, seem to verify rather consistently most of these findings and observations.

However, there is also considerable debate over the ability of various transit administrations to gauge realizable fare elasticity due to the fact that transit mode fare changes often occur across several modes simultaneously, and the elasticity effect on individual modes is clouded by this problem.

Evolution of Models

Originally, transit demand and traffic flows were analyzed with tools that, at their core, used the gravity model, a concept formalized in the 1950s by researcher Alan Voorhees. This stated that increasing distance between two transportation points yielded decreasing likelihood of passengers traveling between those two points. In the model, the concept of “distance” could also be interpreted as time, or alternately as cost. Judged from the point of view of fare elasticity, where fare is increased, ridership is most likely to decrease in proportion.

This theory has held up well in general and has supported many large and small decisions in transportation planning and the administration of fare

levels, service extensions, and related factors. Its utility has flagged somewhat, however, in analyzing systems with a multiplicity of external and internal factors, such as complex demographic makeup in a market, intermodal inputs and influences, ecological and environmental concerns, and the like.

In his 2013 scholarly review and synthesis *Understanding Transport Demands and Elasticities*, researcher Todd Alexander Litman, with a focus on serving the transit authorities of Victoria, British Columbia, began by establishing a broad set of transport demand-affecting factors derived from six general categories of market and social context. Within each of these six categories, Litman identified the following range of factors:

1. Demographics, including the number of people (residents, employees, and visitors), employment rate, wealth/incomes, age/life cycle, lifestyles, and preferences
2. Commercial activity, including number of jobs, business activity, freight transport, and tourist activity
3. Transport options, including walking, cycling, public transit, ridesharing, automobile use, taxi services, telework, and delivery services
4. Land use, including density, mix, and walkability.
5. Connectivity, transit service proximity, and roadway design
6. Demand management, including road use prioritization, pricing reforms, parking management, user information, and promotion campaigns
7. Prices, including fuel prices and taxes, vehicle taxes and fees, road tolls, parking fees, vehicle insurance, and transit fares

Of the above factors and categories, it can be said that most are transferable from one market to another, so long as the administrators of the analysis feel confident that each of their local conditions match the definitions.

Some jurisdictions will, of course, be less interested in many of the factors listed here; they can simplify and substitute like for like in order to produce a modeling system that most accurately reflects the challenges and backdrop of their actual marketplaces. Thus, the data inputs for such a

model can be tweaked to account for unusual (from a regional sense) levels of automobile ownership, for areas of extreme traffic congestion, or to test trip time indices, parking availability, and prices in areas along the transit routes being studied, and many other variables. This type of framework can reliably be mixed and matched to emphasize and de-emphasize certain influences. Investigators have a free hand to change the weighting of factors so that data input for a given study results in outputs that yield realistic answers to the questions that the local transit officials are mandated to explore or are most interested in answering.

It may be that in one region, transit customers are faced with few alternatives; their apparent tolerance for higher transit rates could be masking their just-below-the-surface dissatisfaction with the transit equation they feel they must put up with. This can engender a risky sense of false confidence on the part of transportation authorities in that region, and the introduction of a competitive service with low cost of entry—for instance, an express bus operator with its markedly scant infrastructure needs—could suddenly reveal how loyalty to and satisfaction with the main transit system had been undermined.

In a similar manner, a string of severe weather events could cause repeated intense disruption of a long-standing transit system, compelling riders to seek alternatives. Once the dislocation has passed and the transit system has been fully restored, however, the transit authorities may find that a gap has opened in anticipated ridership levels. It may be that some part of this gap represents riders who have developed a satisfactory alternative that they elect to stay with, even in the face of fresh rounds of fare-cutting by the transit authority.

In such a case, the inputs of income level, transportation infrastructure, and other factors will seem to be identical to the status of the market prior to the series of storms—but the weighting of these factors will have to be entirely reconsidered, at least as they apply to that segment of the former ridership that has “flown the coop.”

Service increases and fare reductions appear to be the two most powerful ways to increase ridership of public transit systems. The effect has, in a number of cases, been shown to be especially pronounced when the metropolitan area under study happens to be experiencing overall economic and job growth.

Many studies in various markets and diverse contexts and environments seem to have validated these commonsense findings.

However, the question remains over how to balance transit system fiscal soundness and how to measure the optimal fare-price level a system can achieve while still retaining a critical bulk, if not most of, its extant ridership. The concomitant question is how thorough and of how high a quality must service levels be maintained in order to support this optimal balance.

Angles of Approach

In addition to the various types of demand-affecting factors, there are other ways to approach the data available in a transit market. For example, some types of trips are valued higher or lower than other types. An emergency trip would be ranked as the highest-value trip and thus be the most resistant to fare increase. Commuting to work is generally the highest value after emergency travel.

In a 1980 to 1981 study within the Southern California Rapid Transit District (SCRTD) in and around Los Angeles, the relative fare elasticity distinction of these value types was starkly revealed as the result of a fare increase regime. All aspects of the fare structure were altered at once, including cash fares, transfers, monthly passes, and special user discounts. The average fare increase amounted to 27.3 percent; the overall ridership across SCRTD immediately declined by 1.9 percent. Revenues, however, rose by 24.5 percent and stabilized.

Among the clearest results was that riders making work trips exhibited no fare sensitivity—in fact, their frequency of ridership increased during the period of the study. Those riders making non-work-related trips decreased their frequency of use. Demographically, those transit riders with low incomes, those with no available cars, and the elderly were less likely to decrease or discontinue their SCRTD use; in essence, these riders assigned a higher value rank to non-work trips than other groups did.

Value rankings such as these can be plotted visually. Further along the descending value curve from emergency and work trips would come commuting to school, major shopping needs trips, travel to special events and socializing trips, and, finally, spontaneous entertainment or shopping trips.

By assigning a given value to each type of trip, these value points can be plotted against fare prices.

The result will be a demand curve, showing how many or how frequently a trip type will be taken. This demand curve reveals price sensitivity; it can be plotted using real inputs in a test of different fare prices and by counting the number of trips that result. In a London Transport ridership analysis that covered two decades of activity (1970s and 1980s) on both the Underground and surface bus systems, demand curves were developed to account for such value-oriented system and context factors as run-miles for each mode, employment, retail sales, tourism, auto ownership, and key one-time events.

In such a study with its value-focused bias, fare price, can be plotted against number of trips, or consumption, with a steeper downward curve revealing lower demand elasticity. That is, the drop-off in consumption is greater in reaction to higher fares. When the curve is more gradual, the drop-off in consumption is more elastic; the riders are not cutting trips as quickly in reaction to the higher fares. The curves can also be plotted against time, which can reveal the persistence or dwindling of demand-elasticity impact as a result of fare increase.

In the London Transport case, for instance, it was demonstrated that two-thirds of the change in demand occurred immediately in the case of the bus mode, with the remaining change taking shape over the course of one year or somewhat longer. However, virtually all of the change in demand for the Underground mode occurred immediately.

The efficacy of fare changes upon demand levels can also be tested within distinct segments of a transit system. Beginning in the 1970s, for example, transit administrations in Portland, Oregon, and Seattle, Washington, tested the viability of fare-free zones in downtown areas where municipal government and business leaders were interested in building up attendance and transactions among the core retail and cultural attractions. In each case, it was found that both local residents and transient tourists were increasing their use of outlying, fee-based segments of the transit systems due to their interest in the downtown attractions and their desire to access the fare-free segments of the transit systems.

Fare-free ridership in the downtown zone of Seattle reached an estimated 7.6 million annual trips, or 25,000 per weekday. This represented a 200 percent increase and created a demand surge at peak times that was met largely by adding bus service in the core business district. Additionally,

an increase of up to 2,000 daily transit trips were recorded outside the fare-free zone, helping cover the costs of the free service.

In Portland, where the fare-free zone was accompanied by fare changes in other segments of the system, it was found that more than 40 percent of survey respondents had increased their use of the metropolitan transit system. Of these, 35 percent credited a newly introduced monthly discount pass option, 27 percent credited the fare-free zone directly, about one-fifth credited a new flat-fare offer, while another one-fifth credited increased service overall.

TRANSPORTATION

Transit Fares, Media and Collection Systems and

Cash is the simplest way to pay for transit fares, and many bus, subway, and commuter rail systems began operations by accepting only cash; some continue to accept it today. However, cash has several disadvantages, including the risk of theft, delays caused by the time required to make change and confirm that the correct fare was paid, mechanical problems with collecting paper money (especially in the United States, where dollar coins are not in common use), and the time and effort required to regularly collect cash from the fare boxes and count and sort it before depositing it in the bank. Studies have also shown that passengers are more sensitive to increases in fares when they are paying cash than when paying by other means. For these reasons, many transit systems offer alternatives to paying fares in cash, most commonly through tokens, passes, or electronic stored-value cards.

Fare Collection

Fares may be collected before the passenger boards the vehicle, at the time of boarding, after the trip is under way, or when leaving the vehicle. The first method is common in commuter rail and subway systems, as well as in all systems that use unlimited-ride passes (in which case the fare is collected when the pass is purchased).

Subway systems often have a turnstile or gate system that requires paying a fare to access the train platform, or they may use the self-service fare collection (SSFC) method, which is also used by many rail systems. In an SSFC system, there is an open train platform (that is, there are no barriers to prevent anyone from entering it) and passengers purchase tickets in advance. They then cancel them in a machine shortly before boarding.

The canceling process stamps a date and time (and possibly a location) on the ticket, so it cannot be used again, and the honor system—along with the sporadic presence of train inspectors—encourage travelers to abide by the rules and pay their fares. One major advantage to SSFC is that all doors may be used to board the train, reducing delays; another is simpler construction of stations, because turnstiles or fare gates are not required.

Some cities (for example, Curitiba, Brazil) use a bus rapid transit system in which passengers prepay their fares at above-ground stations equipped with turnstiles and a raised waiting area separated from the sidewalk. Because passengers must pay a fare to enter the station, they can go directly onto a bus once they are inside the station.

However, it is more typical for bus systems to use a “pay as you enter” system, in which passengers pay their fare as they board the bus and pass by the driver. They may deposit money into a farebox or swipe a stored-value card through a card reader. Although this system is simple and solves the problem of limiting access to people who have paid a fare, it can cause delays in boarding, as each fare must be collected before the passenger can board.

In some systems (for example, the public bus system in Bangkok, Thailand), the problem of delays is avoided by allowing passengers to board and then having a fare collector get their fares while the bus is traveling; however, this system is labor intensive and thus expensive, particularly in high-wage countries. Collecting the fare as the passenger exits may also help prevent delays and is most practical on routes where many people board at one or a few locations but get off at many different locations, so the fare collection process is more dispersed.

If a route collects passengers from many locations and delivers them to a central location in the morning, with the reverse in the evening, as is typical of many commuter routes, the “pay as you enter” system may be used in the morning and “pay as you exit” in the evening. The “pay as you enter” and “pay as you exit” systems may also be combined on a single trip, if the transit system consists of multiple zones. In this case, passengers pay one fare to board and a second fare if they exit the system after the zone marker.

Subway and Bus Tokens

Many transit systems use tokens, coinlike objects of a distinctive size and weight, which can be collected through turnstiles or fare boxes. Using tokens speeds the fare collection process, avoids the need to make change, and allows the transit system to set fares without regard to the coinage needed to pay them.

For instance, when the New York City subway system introduced the subway token in 1953, the

turnstiles that collected fares had been designed to accept only a single coin. That system had worked when the fare was 5 cents, and later when it was raised to 10 cents, because the turnstiles were set to accept first a nickel, then a dime. However, when the fare was raised to 15 cents in 1953, engineers could not manage a way to alter the turnstiles to accept two different coins for a single fare (a nickel and a dime), and thus the token was invented as a sort of alternative currency that was sold for 15 cents. The city of Baltimore, Maryland, adopted tokens for a similar reason, when the fare was raised from 5 cents to 6 cents in 1919.

New York stopped selling transit tokens on April 12, 2003, and by that point only about 8 percent of rides were paid for by tokens, with most riders using the electronic, stored-value Metrocard, which had been available since 1994. Besides putting an end to a crime called "token sucking" (jamming a turnstile so tokens would not go through, then stealing them by sucking them back up through the slot), ending the use of tokens also eliminated the cost and labor involved in delivering them to token booths, selling them to passengers, and removing them from the turnstiles.

Ending token sales also eliminated the risk of theft during the transportation of tokens, a significant consideration because tokens were valued at \$1.50 each by 2003. Finally, the city had lost considerable revenue over the years resulting from counterfeit tokens, the use of foreign coins, or tokens from other systems that were close enough in size and weight to be substituted for subway tokens.

Announcing a fare increase without changing the token also presented a problem to the transit systems, because riders could easily hoard tokens purchased at the lower price and use them after the price was raised. To attempt to prevent this, officials sometimes announced that the token would be changed at the same time as their fare increase, then apparently reversed this decision at the last minute.

Not counting commemorative tokens, five token designs were used in the New York City system over a 50-year period; the first two were a metal disc with a "Y" cut out (to change the weight of the token so a coin or slug could not be substituted), followed by a solid brass token, then a bimetallic token, and finally a token with a pentagonal cutout. When the transit token was phased out in 2003,

the fare was raised to \$2 (from \$1.50); to prevent hoarding, subway turnstiles were reengineered to reject tokens, though they were accepted on buses for a grace period, along with the payment of an additional 50 cents.

Today, some transit system sell tokens as one of several ways to purchase fares (for example, stored value fare cards, cash); examples include Toronto, Los Angeles, and Paris. Others have phased out tokens in a manner similar to New York City. For instance, the Maryland Transit Authority, which serves Baltimore, ceased selling tokens in June 2003 and ceased accepting them one year later.

As in New York, the switch from tokens to electronic cards was accompanied by a fare hike; unlike in New York, passengers in Baltimore were allowed to continue to use the tokens for a grace period without depositing additional cash in the farebox.

Passes and Multiple-Use Tickets

Many transit systems offer passes good for unlimited rides within a certain time period, typically one day, one week, or one month. These passes may be simple cards to be displayed to the driver, booth clerk, or fare inspector upon entering the system or upon request. With this system, passes for different periods must be visually distinctive (for example, the March fare pass could have a different color from the February fare pass) to prevent people from easily using a pass that has expired.

Pass systems have proven popular in many cities where they have been introduced. For instance, two months after Atlanta, Georgia, introduced a monthly pass in 1979, the pass was being used by 12.7 percent of passengers and on 17.8 percent of trips; riders polled about their reasons for purchasing the pass cited savings (56.2 percent) and convenience (28.4 percent) as their primary reasons.

After New York City introduced unlimited-ride passes in 1998 (seven-day and 30-day cards) and 1999 (one-day cards), as well as free transfers, subway ridership went up 6.6 percent on weekdays and 11.5 percent on weekends, and bus ridership went up 26 percent on weekdays and 27.2 percent on weekends. When London introduced a Travelcard pass good on the Underground (subway) and bus system in 1983 and 1984, an estimated 20 to 33 percent increase in passenger miles traveled was attributed to the Travelcard.

Pass systems have also been used to promote the use of public transit by groups of people, such as students at a particular school or employees of a particular company; often the school or employer offers the passes at a discount to limit the number of people driving to work or school. These programs have often proven popular.

The University of Washington in Seattle, for example, began offering a discounted unlimited-ride pass (the U-Pass) to employees and students in 1991, in combination with increased parking fees on campus. After one year, vehicle trips to campus were reduced by 16 percent, and transit ridership was increased by 35 percent.

Multiple-use tickets are good for a fixed number of rides and are often sold at a discount compared to buying the same number of rides individually; for instance, the Long Island Rail Road (New York) offers a 10-trip ticket that costs less than buying 10 individual tickets. Paper multiple-use tickets are usually punched or marked by the conductor each time they are used, making it easy to see how many fares are left on the ticket; stored-fare cards may also be good for a specific number of rides, in which case each use is recorded electronically. Some transit systems allow multiple-use tickets to be shared among individuals (for instance, several people traveling together), while others restrict use to only one traveler.

Stored-Value Cards

Many transit systems have adopted the use of electronic, stored-value cards, using plastic cards similar to credit cards. In this system of fare collection, the user buys a card worth a certain amount (for example, \$20), and the cost of a fare is automatically deducted by a card reader each time the card is used. Many systems also allow people to add money to existing cards, and may offer a bonus for putting a certain amount of money on a card (for example, a \$2 bonus when putting \$20 on the card).

Some stored-value card systems require direct contact of the card with the card reader (for example, swiping the card through a narrow slot), while others use radio frequency identification (RFID) technology to communicate with the card reader by high-frequency waves. RFID cards and their readers have the advantage that they are not subject to wear and tear as much as the cards that require contact and do not require the user to swipe the card at a particular speed in order to be read.

Smart cards allow transit systems to collect information about the number of riders entering the system at particular times and locations, information that may be used to plan to improve service. However, because they allow for the collection of information about when and where particular cards have been used, they also have raised privacy concerns. Such systems make it theoretically possible to identify where a given person (or, actually, a given transit card) was used at a particular time.

In fact, such information has been used to defend individuals against criminal charges by demonstrating that they were not near a crime scene at the time of a crime. Encryption is generally used in smart-card systems, but the fact that card-use information is gathered and stored in a central location, where it could be theoretically linked to other data, is a matter of concern for some people.

One concern with RFID technology is that the information stored on an RFID card can be altered by someone with sufficient technical knowledge. In 2008, three students from the Massachusetts Institute of Technology (MIT) wrote a paper demonstrating how to “hack” or reprogram the RFID fare cards used by the Massachusetts Bay Transportation Authority (MBTA) in order to obtain free rides.

The MBTA sued to stop the students from presenting their paper at a conference in Las Vegas, Nevada, arguing that it would violate laws regarding computer fraud and that MBTA authorities should have a chance to review the security flaws in the system before those flaws were made public. However, the students claimed that they would have withheld key information in their talk, and that they should be allowed to present the paper as a matter of academic freedom; a U.S. district court judge agreed with the students, ruling that presenting an academic paper would not violate computer fraud laws.

Advantages of Stored-Value Cards

Implementing a stored-value card system is a major expense for a transit system but offers such advantages that many systems are converting exclusively to stored-value cards, as well as adding them as an option for fare payment.

One obvious advantage of stored-value fare cards, from the point of view of the transit system

management, is that fares can be easily changed without the need to issue new tokens. Instead, when a new fare structure is implemented and the equipment updated, the correct amount for the new fare will be automatically deducted from an individual's farecard. Passengers are also less sensitive to price changes when using stored-value fare cards, as opposed to paying a cash fare.

Another advantage of stored-value fare cards is pricing flexibility. Transit system pricing has multiple competing goals, including raising revenue, promoting use of the transit system, charging riders a fair amount based on their circumstances, and shifting ridership from peak periods of usage to less crowded periods. One strategy to achieve these goals is differential fare pricing. Examples of this include charging different fares at different times and days, for different lengths of trips, for different classes of riders (for example, students, senior citizens, handicapped people). While these goals can be achieved with other methods of fare collection, the use of stored-value electronic fare cards makes them particularly easy to achieve.

Stored-value cards facilitate transit system integration, including transfers among different types of transport (for example, subway to bus). Although a transit system using cash or tokens can offer transfers among lines or modes of transit by the use of paper transfers, the process is simplified with stored-value cards that can register a transfer (including checking for time or route limitations) without subtracting further money from the card.

Stored-value cards can also check for valid transfers (for example, that the allowed time period has not expired, and that transfer is allowed between the routes in question), while paper transfers require a system of visible coding that may include the time, line, and direction for the trip on which the fare was paid, but the driver or fare collector must inspect each transfer visually to see if it is valid.

Stored-value cards also offer more flexibility in terms of offering unlimited-ride cards, usually for a period of time such as one day, one week, or one month. While this can also be accomplished by issuing a pass that the passenger displays to the bus driver, train conductor, or token clerk, electronic unlimited-use passes have the advantage of automating the process. Stored-value cards also allow unlimited-use passes to be sold for any period, not just a calendar week or month.

For example, a 30-day pass could be good for any consecutive 30-day period, or a day pass for any 24-hour period.

Transit Finance

Although most transit systems charge fares to riders, these fares often do not provide sufficient revenue for the system to remain in operation. For this reason, a variety of other financing sources are used, including federal and state general tax revenues, specific state or local revenues (e.g., a gasoline tax), and/or the issuance of various types of bonds. Some transit systems have also tried different pricing strategies to increase revenues, and local governments have entered into public–private partnerships as an additional way to finance aspects of their transit systems.

History

Many transit systems that are now primarily or entirely public began as private, for-profit systems, with government involvement initially limited primarily to regulation. In fact, in 1945 only 2 percent of transit systems and 16 percent of transit vehicles in the United States were publicly owned; by 1985, the public share had increased to 30 percent of the systems and 80 percent of the vehicles.

Loss of ridership played a role in the shift to public ownership. While transit use peaked in the United States in the 1940s, with an annual ridership around 24 billion nationally, by 2000 ridership had fallen to below 9 billion. The loss of ridership was reflected in declining revenues for transit systems and motivated the search for other sources of funds. As late as 1960, fares provided most of the operating revenues for transit systems, but this share declined over the next several decades to 54 percent by 1975 and 36 percent by 1988.

The Urban Mass Transportation Act of 1964 provided federal assistance to upgrade transit equipment, in part because deterioration of existing transit systems raised fears that they might cease to operate at all. At about this time, many cities created public transit authorities, purchasing the assets of private transit companies and operating them with the services and fare structures decided by governmental or quasi-governmental decision makers.

In 1974, the federal government began offering operating assistance as well, and by 1988, fares only paid about one-third of operating costs (36 percent), with the rest coming from state and local governments (52 percent), the federal government (6

percent), and other operating revenues (6 percent). However, federal support for public transit began to decline in the early 1980s, and the difference was primarily made up by state and local governments, using a variety of revenue sources including sales taxes, fuel taxes, property taxes, general tax revenues, and the proceeds of lotteries. In general, non-urbanized transit systems receive a higher level of subsidy than do urban systems.

The amount of transit operating expenses that should be covered by fare revenues is a matter of debate. At one extreme, some argue that fares should be high enough to cover all expenses, a solution that is neither practical nor equitable in most areas, as other forms of transportation, including private automobile travel, receive numerous subsidies. On the other extreme, some argue that public transit should not collect fares at all—instead it should be offered as a free public service.

While free or nearly-free service has been offered in some systems (for example, Moscow and Mexico City), this has not proven sustainable other than in limited cases, such as fare-free zones in central business districts or transit services provided around airports, when a primary aim of the transit service provided is to reduce automobile travel and relieve congestion.

Fare Revenues

Nationally, the average portion of a transit systems' expenses paid through farebox recovery from 2002 to 2004 was 35 percent, with a range from 9 percent (Austin, Texas) to 60.6 percent (Washington, D.C.). Internationally, only a few transit systems are self-supporting, including those of Singapore and Hong Kong. The estimated rate of subsidy for Europe is 44 percent, and the rate for Canada is 56 percent.

Aside from arguments about fairness (people with lower incomes, the elderly, and the disabled may depend on transit more than high-income, working-age, able-bodied people), the relationship between fares and revenues is not always straightforward. Although it may seem obvious that raising the fare should increase revenues, this is not necessarily the case, as ridership may decline enough to offset the additional revenue gained from each fare.

Although the price elasticity of demand for transit services varies across many conditions, the

Simpson & Curtin formula is a commonly accepted method to calculate changes in aggregate ridership expected with changes in price as

$$Y = 0.80 + 0.30X$$

Where Y = the percent loss in ridership after the change in price compared to the ridership before the change, and X = the percent increase in fare compared to the prior rate. By this formula, a 10 percent increase in fares would result in a 3.8 percent decrease in ridership, because

$$Y = 0.80 + 0.30(10) = 3.8 \text{ percent}$$

Studies of fare changes in particular cities have found this to be a reasonable average estimate, although bus elasticities are generally about twice as high as rail and subway transit elasticities, possibly because other alternatives such as driving an automobile are more easily substituted for bus service, and because urban rail transit may offer advantages such as speed and convenience that cannot be replicated by other forms of transit. Other factors that have been found to be related to fare elasticity include the population of the service area and time of day (peak versus off-peak travel).

One method some transit systems have adopted to increase revenues is to reduce rather than raise fares for selected groups by offering deep discounts (for example, staff members and students at a university).

Characteristics of typical deep discount group pricing (DDGP) programs include offering a pass good for unlimited rides for all members of a group at steeply discounted pricing (for example, 40 percent to 94 percent off a comparable pass available to the public); some also include guaranteed-ride-home programs (offering alternative forms of transportation if an employee works beyond the transit system operating hours).

DDGP programs in Denver, Colorado; Berkeley, California; and the University of California, Berkeley, were found by one researcher to be generally successful in increasing operating revenues; specifically, he found that DDGP programs consistently resulted in higher revenues per board (compared to the systemwide average) or higher total revenues for the transit system compared to similar markets without a DDGP program.

Tax Revenues

One important source of funds for transit systems is federal subsidies, which rose substantially for several decades beginning in the 1970s, then declined. Measured in constant 2000 dollars, federal transit subsidies in the United States rose from \$4.5 billion in 1975 to \$12.3 billion in 1992; by 2006, the federal subsidy had dropped to \$8.1 billion. However, the 1974 program that offered federal operating subsidies to local transit systems required a 50 percent match from other sources of funding (including fare collection and state and local funding), so transit systems have for decades needed to find ways to raise funds independent of federal subsidies. In addition, almost half of federal funding for transit goes to just a few states: New York, California, Massachusetts, New Jersey, Pennsylvania, Illinois, and Maryland.

In 2006, almost all (94 percent) states provided funding for public transit. Combined, the states provided \$11.1 billion in transit funding, more than twice as much as the \$4.8 billion provided by the states in 1995. In 2006, the most common sources of state revenues to support transit included gas taxes (19 states); the general fund (12 states); bond proceeds (10 states); taxes on rental cars and motor vehicle sales (10 states); fees for automobile registration, titles, and licenses (10 states); and general sales taxes (9 states). However, as with federal funding, the bulk of state funding for transit is provided in just seven states—New York, California, Massachusetts, New Jersey, Pennsylvania, Illinois, and Maryland—which together received \$7.6 billion in funding in 2004, compared to \$1.7 billion for the remaining 43 states and Washington, D.C. Transit ridership often increases during a recession or other long period of economic stagnation and/or unemployment, while tax revenues decrease during such times. This fact has motivated many transit systems to seek a variety of sources of funding. In addition, concerns about air pollution, health, and quality of life have also created broad interest in finding ways to make public transit financially stable, and in some cases to increase transit services as well.

Numerous options exist to finance public transit, each offering both advantages and disadvantages. General obligation bonds are issued by a government entity, and repaid from general tax revenues; they can offer lower interest rates (and hence are a cheaper way to borrow money) than some other types of bonds because they are backed by the full

faith and credit of the issuing body. However, the bonds must be paid back even if tax revenues are lower than anticipated, so other programs may have to be cut to compensate.

Revenue bonds are repaid by specific revenues (for example, the fees generated by a parking facility whose construction was financed by the bonds), and thus are riskier and generally must offer higher interest rates than general obligation bonds; however, they are less risky for the government because the bonds are not backed by general revenues.

Tax increment bonds are based on the principle that investment in transit generally results in higher property values, and thus increased property taxes; this is advantageous in that some of the benefits of the transit construction are used to pay back the bond, but risky in that the expected increase in revenues is not guaranteed.

GAN (Grant Anticipation Note) bonds borrow against the expected future value of federal transit funding and apply only to metropolitan areas with populations of 200,000 or more. Because of the predictability of federal funding (which is determined by a formula), these bonds have a low interest rate, but this type of financing means that future funds are being spent before they are received and will thus not be available to carry out other projects.

Public-private partnerships are another way to fund public transit. In this system, a private entity carries out specified aspects of a transit project after raising the capital necessary to complete the project, and the entity is allowed in return to collect user fees and/or receive payments from the government. Public-private partnerships allow government to shift some project risks onto the private entity, but it is generally a more expensive way of raising revenue than issuing bonds. In addition, the government cedes some control over the project to the private entity.

Transit Industry, Economics of

Revenues collected from the fare box are never enough to cover the operating costs of a transit agency's services. The percentage of operating costs that is covered by fare revenues is commonly known as the "farebox recovery ratio." This ratio can be measured, for example, by route, by type of service (local, express, etc.), by mode (bus, light rail, heavy rail, etc.), or for an entire system.

In some cases, it may be possible for some routes or service types to generate enough in fare revenue

to cover the operating costs associated with those services; however, in general, no transit agency in the United States collects enough in fares to pay all of its operating costs, much less capital costs. As a result, a transit system's farebox recovery ratio is less than 100 percent.

On average, transit fares tend to cover only approximately 25 percent to 35 percent of all operating costs. To pay these costs, transit agencies must generate other types of revenue and also must rely on subsidies at the local, state, and/or federal levels.

Transit Operating Costs

To put services on the street, transit agencies must pay operating costs associated with general administration and maintenance, as well as the actual operation of the transit service. Administrative costs include functions such as office management, human resource administration, transit service development and planning, market research, legal services, customer service, finance and accounting, and other data processing functions. Transit agencies often try to keep administrative costs low so that as many resources as possible can go toward maintenance and operation of the service.

Maintenance expenses can be generally classified as those relating to vehicle maintenance or to non-vehicle maintenance. Vehicle maintenance costs are those costs directly related to maintaining the transit vehicles for service, including inspections, maintaining vehicle maintenance records, compiling vehicle performance data, training maintenance personnel, vehicle repairs, and other general vehicle servicing. Nonvehicle maintenance costs are those related to maintaining transitways, facilities, buildings, grounds, and equipment, as well as the related supervision, clerical support, and training.

The largest share of operating costs is associated with the actual operation of the transit services. Within this category, the largest element tends to be the cost of the transit vehicle operators, in salaries and benefits. Other costs in this category include transit operations administration and support, vehicle movement control (also known as dispatch or transit vehicle traffic control), activities associated with the scheduling of transit service, activities related to ticketing and fare collection, and system security.

While there is pressure to keep administrative costs low, transit agencies are always actively trying

to find ways to keep all operating costs down. It is a challenge for the agencies to offer the types of services demanded in their communities within the funding constraints from fare policy and government subsidies. Trade-offs must often be made, for example, between offering more service covering a larger geographic area and offering service that is more concentrated in a smaller geographic area but more intensive (that is, more frequent service and/or with longer operating hours, called the service span).

Fares and Other Directly Generated Revenue

To take a trip on transit service, passengers must pay a fare. Transit fares may vary by mode or type of service, by time of day, by type of passenger, or by other factors. Sometimes, passengers must also pay an additional fare to transfer to another route or type of service (known as a transfer fare).

Fares can be paid on a per trip basis in cash, or passengers can usually elect to purchase a prepaid pass from a range of options, including passes that are valid for a given number of trips and passes that are valid for a certain length of time (such as daily, weekly, or monthly). Typically, passes provide extra value to the passenger by lowering the average fare paid per trip.

Other types of passes offered by transit agencies include discounted passes for students, the disabled, and the elderly; people in these groups also tend to pay a discounted per trip fare. Some transit agencies may allow passengers in certain groups, such as the elderly or students, to ride free.

Agencies that operate in cities with universities sometimes have an agreement with the university to allow students to ride free in exchange for a bulk payment, usually comprised of funds that originate from student fees. In some cases, a transit agency may decide to operate all or part of its service fare free. Clearly, the fare policy of a transit agency will have a significant impact on the total amount of fare revenue it generates and, subsequently, its farebox recovery ratio.

In addition to fares, transit agencies often look for other ways to generate revenue on their own. One common way that transit agencies generate additional revenue is through displaying advertising materials on transit agency vehicles and/or property (such as at stations or on stops/shelters). Other directly generated revenues may result from park-and-ride revenues, interest income or

investment earnings, concession sales at stations or on vehicles, revenues from leasing parking facilities or portions of stations or other facilities for private use, and donations or other private grants.

Sometimes, the transit agency may be designated as an independent political entity or special taxing district, which provides the agency with the authority to directly levy taxes, such as property, gas, or sales taxes. These types of taxes are considered dedicated to transit at their source.

Local and State Revenues

As stated previously, revenues from fares usually cover approximately 25 to 35 percent of the average U.S. transit agency's operating expenses. While agencies can generate additional revenues directly, there still remains a need for additional subsidies. Local and state governments often provide additional revenues for the operation of transit services. At the local level, a government entity may elect to provide a subsidy to the agency out of the entity's general revenue fund. Other options at the local level include revenue from income taxes, gas taxes, sales taxes, property taxes, hotel taxes, utility fees, and parking fees and fines, among others. In contrast to taxes directly levied by a transit authority, these other local taxes are not necessarily dedicated to transit at their source.

Many state governments also provide funds for the operation of transit services. Such funds may originate from taxes (for example, sales, income, or gasoline), vehicle registration fees, employer or payroll taxes, lottery or casino revenues, vehicle leasing and rental fees, and toll revenues, among others. It should be noted that the lists of potential local and state funding sources provided above represent commonly used funding types and are not exhaustive. Transit agencies often work with their local and state governments on various strategies for funding public transit services.

Federal Revenues

The federal government has a role in funding the operation of public transit services in the United States. Transit agencies can apply for a range of federal grants to fund portions of the capital requirements for transit services, as well as the operating costs.

Currently, two major sources of federal transit assistance include the Federal Transit

Administration (FTA) Urbanized Area Formula Program (§5307) and the FTA Other than Urbanized Area Formula Program (§5311). These two funding programs provide funds for capital projects planning, capitalized operating assistance (for example, preventive maintenance), and operating assistance in urbanized areas (UZAs) with populations smaller than 200,000 and in non-UZAs with populations less than 50,000. It should be noted that recipients of these grants are required by statute to submit reports to the National Transit Database (NTD). Data from the NTD are available publicly and represent a good, comprehensive source for transit statistics and other information.

In addition to funding programs available from the FTA, transit agencies may also be eligible for funding from other U.S. Department of Transportation programs. In recent years, however, the amount of funds available at the federal level for transit operating assistance has declined, resulting in a greater reliance on funds from the state and local levels. In addition, transit agencies increasingly seek out other new, innovative ways to fund their services.

Innovative Cost and Funding Strategies

Recent economic conditions have found transit agencies in situations where they have had to increase fares, cut service, or both. Declining shares of federal transit operating assistance, budgetary pressures at the state and local levels, and increasing labor, fuel, and other costs have resulted in the need for transit agencies across the country to look for other ways of funding transit services.

In the transit industry, much research has been done on innovative funding strategies and, in addition, transit agencies can learn from other agencies' experiences with novel ways to keep costs down and generate additional revenue.

One way that some transit agencies have been successful in reducing costs has been by contracting out some or all of their services to private transportation providers. In many cases, the public agency still maintains control of and plans the service, while the private provider is responsible for the actual operation of the service. There are many factors that a transit agency must consider in determining whether privatizing all or part of its services will be beneficial and result in the expected cost savings.

A common strategy for generating new revenue involves the creation of public-private

partnerships, which essentially allow the public transit agency to leverage private resources to better achieve its objectives. An example is when the public transit agency and one or more private organizations collaborate on the joint development of a transit station or other facility. Other examples include situations where entities from the private sector assume a larger role in the planning, financing, construction, operation, and maintenance of public transit facilities.

systems, and a range of other types. The common thread is the transference of and access to information that helps managers, administrators, workers, customers, funders, and planners make good decisions about the transit network appropriate to the manner in which they interact with it and with each other. Transit information systems also facilitate communication between multimodal transit networks, as well as between the networks and their external partners, whether suppliers, oversight agencies, or other entities.

Passenger Friendly

Passengers benefit by being able to access transit information through a variety of places, modes, and times. Each time a passenger seeks to plan a trip, check on route conditions, determine a fare, or gain other information, the administrators and operators responsible for the transit information system have an opportunity to deliver a customer benefit. When they realize such benefits, customers are more likely to enjoy increased service quality satisfaction—the single most important factor in improving all other ridership metrics.

Passenger information systems stem from origins as simple painted signs and printed schedules, supplemented by public address speakers, visual cues at stations and on rolling stock, and occasionally in mailings and public awareness advertising campaigns. In the contemporary sense, all of these modes are electronic in form and, increasingly, digitally enabled. Destination indicator boards within subway cars, on trains, and in buses, as well as on station platforms, can offer a route map showing active and inactive destination stations; this essential information can be augmented with data such as estimated arrival times, time to next station, next available service, and the next connecting service.

LED illumination has been widely adopted for these devices, boosting reliability and readability while conserving electricity. These display boards can be used in conjunction with digital voice messages and, in some of the more advanced installations, can be linked to wireless Internet service.

Ideally, these systems provide passengers with real-time information, although versions representing most of today's installed base provide only standard, preprogrammed station-to-station announcements. Still, the majority of these systems

Transit Information Systems

Transit information systems can include passenger information systems, dispatcher and driver communications and information systems, network monitoring models, internal auditing and planning

are complemented by some means, generally auditory, of delivering such information as reasons for delay, the cause of a disruption, and any emergency or service-change updates.

Next Phases

Stationary transit information devices, such as interactive kiosks, can provide an extra measure of customer satisfaction during times when they are not being actively transported on the network. A system installed in 2012 in New York City by the Metropolitan Transportation Authority, for instance, features On the Go! kiosks that show-case route maps, line status, and ancillary trip planning information such as entertainment and cultural attractions by neighborhood. All of this information is produced in a visually stimulating format. Touch screen technology and colorful, large-aspect screens have made the pilot project a notable success, one that is being expanded.

There exists a multitude of opportunities to extend the reach and function of such installations. A new generation of self-service ticket kiosks, for instance, could double as travel information centers. Beyond simply enabling people to purchase a fare or refill a fare card, the enhanced kiosk could provide travel advisories in real time and suggest alternate means and routes for the passenger to reach destinations.

Radio frequency identification (RFID) systems, which use a barcode recognition technology, can already handle transactions in conjunction with smart cards. These can be tailored to provide personalized information upon recognition of the individual who is presenting the card. RFID systems are limited to very short distance scanning pickup—dubbed near-field communications, or NFC—but through constantly innovating “tag” technology, the sophistication of this data transfer platform is being leveraged to provide for imaginative new applications.

A trial in the Bay Area Rapid Transit (BART) system in San Francisco employed RFID hardware and protocol to enable commuters and other travelers to purchase train fares at BART subway stations equipped with turnstiles that read the RFID chips embedded in their cell phones. This is an extension of RFID-enabled smart card technology that opens the gate to information exchange beyond a simple fare transaction. BART officials have considered

Electronic information systems provide arrival and departure times as well as information about delays and disruptions. The same information can be delivered to passengers through the Internet, mobile phones, or self-service touch screen kiosks.

building out the system with such features as reward programs and linking to retailers, among other features the system could enable. This type of system is a variation of versions that are in much wider use in some Asian metropolitan areas, such as Hong Kong.

Network Information

Nearly all transit units, or vehicles—trains, trams, subway cars, buses—feature communications equipment in the driver cab. Usually these installations include straightforward telephone or radio connections to dispatchers, as well as internal public address systems that may have alternate channels for exchanges with other transit personnel such as conductors. The equipment typically includes a transmitter built into the vehicle.

Drivers on some transit vehicles also deploy pre-recorded digital voice messages for the benefit of the passengers. On occasion, they add their own live notifications in order to provide actual route condition or vehicle situation information. More frequently, they use the internal public address system to manage passenger behavior and make suggestions and announcements.

There are also emergency transmission systems. Some bus drivers, for example, can activate a type

of silent alarm that combines a wireless alert beacon with an emergency message displayed on the external visual readout panels, such as “Call 911. Emergency.” This type of alert can gain the assistance not only of central control dispatchers but also, potentially, of passersby, who can help guide emergency responders, thus cutting response time.

Dynamic Mobility

Prototypes of far more advanced information systems are in various stages of research and design. For example, the Intelligent Transportation Systems Joint Program Office of the U.S. Department of Transportation’s Research and Innovative Technology Administration (RITA) is engaged in various development projects it manages under the rubric of dynamic mobility applications. The goal, according to RITA, is

making surface transportation safer, smarter, and greener by leveraging wireless technology capabilities in an interoperable communications network environment to provide safety, mobility, and environmental benefits to the transportation community and the traveling public.

RITA has oversight for research projects that are testing dynamic mobility software applications to allow traffic managers to better anticipate transit system problems, use predictive modeling to aid decision making, and monitor impacts of decisions in real time by way of dedicated short-range communications and related wireless methods.

To test such ideas, various types of probes, sensors, and transmitting nodes are embedded in vehicles tied together through existing networks. They are then linked via the new data exchange systems. Many such RITA programs are still in the stage of defining metrics for single-mode and multimodal performance and at the same time identifying highest-value public sector applications to prioritize.

Transit Lines/Networks

There are many ways to organize a transit system, and the choice of how to do it is made by balancing numerous factors, including pre-existing travel networks, varying demands for services in different parts of a region, efficiency and economy, and comprehensibility to users. Among the most common types of organization in use for transit systems are rectangular grids, radial grids, and polycentric networks.

Grid Systems

The rectangular grid system, with streets of uniform width regularly spaced and laid out parallel or at right angles to each other, is one of the oldest city

layouts known. There is archaeological evidence that it was used in ancient Egypt, in the Babylonian empire, in China, and in ancient Mexico City, among other places.

Many American cities were also laid out in a grid pattern, or the grid pattern was imposed at some point in the city's development. For instance, in New York City, the Commissioners Plan of 1811 imposed a grid pattern on the island of Manhattan north of Houston Street, while the older streets south of Houston retained a much more irregular and random pattern. When public transportation routes began operation in cities constructed on the grid layout, they naturally followed those patterns as well.

Rectangular grid patterns have many advantages. For one, they offer good transportation service across the grid if riders are allowed to transfer between lines, because no point in the grid lies too far from either a north-south or east-west line. This means that no point in the grid is inherently privileged over any other when it comes to accessibility by public transit, and this is particularly beneficial if an area has multiple key areas of activity.

Grids also work best if the lines are anchored by major destinations at their endpoints, because that means there will be lots of people riding to the end of the line. Grids are also intuitively easy to understand, although they have the disadvantage that they work best in relatively flat regions. San Francisco is a famous example of a city that laid out its roads on a grid system without considering the underlying topography; the result was many roads running up and down extremely steep hills, a reality that motivated the development of the city's signature cable car system.

Another type of grid is the polar or radial grid, which centers on a single area (for example, the downtown area of a city) with transit lines laid out in concentric rings around this central area; straight lines cross one another throughout the central area, creating the appearance of a spider web. With this system, areas near the city center are close to one or more transit lines, while areas farther away from the center have a higher probability of being farther from any transit line.

This system has advantages if the central point is truly primary in the travel patterns of the majority of transit users in the area, if areas farther away from the center are less likely to be visited

by people using public transportation, and if it is assumed that alternate transportation (for example, an automobile) is an available option for those living away from the city center. This layout is less intuitive than a rectangular grid but increasingly familiar because many U.S. urban areas (for example, Washington, D.C., and greater Boston) have roadway patterns with this design, in which a beltway or ring road surrounds the city or metropolitan area and a second system of roads leads to and from the city center.

Different transit network designs may favor different types of riders, based on their needs and resources. For instance, higher-income residents may be best served by a radial grid system, in which transit lines are organized primarily to transport people from widely spaced suburban stations into the downtown area, with the greatest amount of service provided during rush hour when commuters are coming to or going from their downtown jobs.

Riders of this type of service may well own one or more automobiles that they can use when they need to go somewhere other than where the transit system goes (for instance, to do their shopping or to visit their child's school) or to go somewhere when the transit system is not operating (for example, to go out in the evening). Lower-income residents may not have their own personal transportation and hence will rely on the public transportation system for all their transportation needs. Such riders are often better served by a rectangular grid system, which provides more blanket coverage of an area and does not prioritize one area over another.

Polycentric Route Networks

In a polycentric network, several areas in a region are considered centers. Centers are often defined in terms of employment, so a center has either a minimum number of jobs, or a job density higher than surrounding areas or higher than a designated threshold of jobs. However, one of these centers could also be a place of government, an educational complex, a convention center, or similar destination where large numbers of people travel regularly.

This type of organization is typical of many American suburbs, and Los Angeles County is often cited as a prime example of a polycentric metropolitan region, because it has multiple job centers, business districts, government centers, and

This photo of the greater metropolitan area of Phoenix, Arizona, taken at night from the International Space Station in low Earth orbit, shows the city's north-south grid layout as outlined by street lighting. Grand Avenue, a major thoroughfare lined with development, transects the grid and provides a transportation link from northwest to southeast. Grids are an ancient city design that work well in flat regions, but variations such as polycentric networks have been found to work better in some suburban areas.

attractions spread out across a wide area and separated by residential areas.

A grid system can work well in a polycentric region because it allows approximately equal access to all parts of the grid. However, the grid layout may be wasteful if too many resources must be expended in providing access to areas of low density and priority.

A polycentric or multide destination route network is an alternative to the grid in areas in which multiple centers require service, and the transit system is arranged with transfer points allowing people to switch from one line to another. Between 1983 and 1998, three transit systems that switched to a polycentric route network all had better performance than most traditional polar grid networks, including increased ridership and lower operating costs per passenger mile. Researchers interpret these results as suggesting that polycentric route

organization may be the best way to serve suburban areas with public transit.

Transit Management and Operations

Transit management is an ongoing process that encompasses development, implementation, evaluation of budgeting, service deployment, performance measurement, and other components of the operation of a transit system. In the largest sense, a transit system includes all vehicles, public and private, that move goods or people from one place to another whether by land, air, or sea.

In practical terms, particularly since the advent of the automobile age, "transit system" has commonly referred to public systems that provide scheduled services on fixed routes via modes that include some combination of bus, trolleybus, vanpool, jitney, and paratransit service; heavy rail, light rail, commuter rail, automated guideway transit, inclined plane, cable car, monorail, and aerial tramway; and passenger-only and vehicle ferries, and water taxis.

Transit managers oversee transit vehicle fleets and coordinate operations with other transportation services. The responsibilities of transit managers include not only the functioning and maintenance of transit vehicle fleets but also such tasks as supplying customer information; ensuring communications between transit departments; checking compliance with federal, state, and local regulations; and collaborating with emergency response

services, traffic management systems, and other operating entities as necessary. The transit manager must be able to make decisions in such areas as strategic planning management, labor relations, maintenance planning, administration, financing, marketing, and fare policy.

Changes in Ownership of Public Transit

Public transit has a long history in the United States, beginning in 1852 with New York City's horse-drawn streetcars. Electric streetcars were introduced in 1888, and mass transit ridership steadily increased through the end of the 19th century and into the beginning of the next. Although the Staten Island Ferry became the first public takeover of a private transit company in 1905 and Monroe, Louisiana, boasted the first municipally owned street railway in 1906, most transit companies were privately owned in the first decades of the 20th century.

That situation changed when the first major decline in use came in the 1930s during the Great Depression. Early in that decade, electric companies, who had acquired streetcars for nonpayment of bills, became major transit providers, but their reign was brief. The Public Utility Holding Company Act of 1935 (PUHCA), among other provisions, limited registered holding companies to business activities directly related to the conduct of their utility operations, forcing them to abandon their interests in transit companies. Congress repealed the PUHCA in 2005.

Transit ridership reached 23.1 billion in 1946, but by 1950, 60 percent of American households had a car. A decade later, with growing numbers of American families living in suburbs, three-fourths of American families owned at least one automobile. The Federal Aid Highway Act of 1956 authorized \$25 billion over a 12-year period to pay for the National System of Interstate and Defense Highways. National mobility was becoming a reality, but Americans were traveling in cars rather than by bus and rail.

The Housing Act of 1961 granted cities \$75 million to purchase failing transit companies, and communities across the country began public operations. By 1972, transit ridership dropped to a low of 6.5 billion trips. The National Mass Transportation Assistance Act of 1974 for the first time authorized the use of federal funds for transit operating assistance, but transit systems were forced

to compete with highways for funding until the Intermodal Surface Transportation Efficiency Act of 1991 earmarked money for transit and pushed multimodal services.

Transit Vehicle Fleets

A key component in transit management and operations involves the scheduling, maintenance, and performance monitoring of fleet vehicles. Transit trends in the United States have shown consistent long-term growth since the early 1970s, although growth by mode is irregular. Transit customers using bus services have grown only about 17 percent over the past four decades, whereas use of heavy rail and light rail has more than doubled during the same period. In 2010, United States transit systems had a combined total of 174,425 vehicles available for service.

Bus service is the most heavily used transit service, accounting for more than half of transit riders. During peak service, more than 66,000 buses were operating in U.S. transit systems in 2010. Slightly over a third of transit riders used heavy rail services with 11,510 vehicles during the same period. But heavy rail service is concentrated in large urban areas, while many smaller cities and suburbs offer bus transit. However, the largest fleet of transit vehicles belongs to the demand-response service with 68,621 vehicles, and this mode is utilized in both urban and rural areas.

In 1990, the Americans with Disabilities Act (ADA) was signed into law, mandating that services and facilities be accessible to persons with physical and mental disabilities that substantially limit one or more major life activities. The ADA covers accessibility to employment, public accommodations, government services and facilities, transportation, and telecommunication. Unlike most transit regulations, adherence to the provisions is not related to receiving local, state, or federal funds for projects. The ADA is civil rights legislation, and the U.S. Department of Justice, not the Department of Transportation, has the responsibility of ensuring compliance.

Noncompliance leaves a transit system vulnerable to lawsuits on behalf of persons with disabilities. By law then, in all areas served by regular route transit service, accessible demand-response service must be provided to persons with disabilities that render them unable to utilize fixed-route

service. Demand-response vehicles that travel on roads and streets but take passengers directly from their origins to their destinations, typically vans, have been the common response to this legal requirement. Often the service is also available to all riders, and some areas operate the service in lieu of fixed-route service during late-night and weekend hours. Since the service was begun only after the passage of the ADA, its growth rate is not comparable to that of longer-established services, but the number of fleet vehicles devoted to the service attests to its popularity.

Whatever mode or combination of modes a transit system uses, transit managers are responsible for preventive and corrective maintenance of the fleet vehicles. In 2008, the Federal Transit Administration (FTA) in conjunction with 14 public transportation providers and state departments of transportation determined that \$10.7 billion would be needed to bring all transit modes nationally into the desired state of good repair (SGR), a state in which all preventive maintenance and rehabilitation needs are addressed and no capital asset exceeds its useful life.

Heavy rail and motor bus vehicles topped the list of priorities, with heavy rail stations, systems, and guideway components and bus maintenance facilities falling next in line. The group found that the actual retirement age of buses, for example, generally exceeded FTA minimums because funding was not available for replacement vehicles. The analysis emphasized that vehicles in less than optimal condition can increase problems such as disrupted service, maintenance costs, and slow speed zones.

The asset management approach that was practiced by many of the most effective transit systems in the 2008 study became standard in 2012 when Congress passed the Moving Ahead for Progress in the 21st Century Act (MAP-21), a funding and authorization bill to govern federal surface transportation spending, which required the FTA to establish a national transit asset management system that, through regulation, will define "state of good repair," set objective standards for measuring the condition of capital assets (including equipment, rolling stock, infrastructure, and facilities), and establish performance measures for state of good repair, under which all direct and indirect recipients of FTA grants will be required to develop a transit asset management plan and use an asset

management system to develop capital asset inventories and condition assessments, and to report on the condition of their system as a whole, including any change in condition since the last report, targets set under the performance measures, and, progress toward meeting those targets.

Capital and Operating Expenses and Funding

Of the \$55.6 billion spent by the transit industry in 2010, almost 68 percent of it was spent on operating expenditures. An additional \$17.8 billion was spent on capital investments (largely purchases of vehicles and equipment, and the development of infrastructure and supporting facilities). Operating expenses are measured by function, such as vehicle operations, vehicle maintenance, non-vehicle maintenance, and general administration. Object measurement refers to the grouping of expenses on the basis of goods or services purchased. Salaries, wages, and fringe benefits for employees of transit agencies account for almost two-thirds of operating expenses.

Funds for transit operations come from a variety of sources: passenger fares, other transit agency earnings, and financial assistance from local, state, and federal governments. For transit agencies operating as a department of the local government, the greater portion of funds—more than half—comes from local and state revenues. Passenger fares and other agency earnings account for another 38 percent. Only 9 percent of operating costs are paid for by federal funds. Federal dollars fund substantially more capital investments, around 41 percent.

Transit funding from government agencies at all levels is the price governments pay for the benefits accrued to the community from transit services. The transit system reduces congestion and helps make possible the efficiency of high-density business development, both of which benefit all members of the community. Over 4 billion gallons of gasoline are saved by the combined reduction in private passenger vehicle miles, reduced automobile congestion, and reduced travel distances. The community also benefits from cleaner air that is the result of the 37 million metric tons of carbon dioxide emissions that transit systems prevent. The U.S. Environmental Protection Agency's Greenhouse Gas Emissions Calculator estimates that it would take 7.2 million acres of new pine or fir forests per year to match the annual carbon dioxide reductions provided by public transportation.

The 7,088 transit organizations, ranging from large multimodal systems to single-vehicle special demand-response service providers, also saved the American consumer dollars in 2010. The 4 billion gallons of gasoline saved annually through public transit, assuming gasoline is \$4 per gallon, saves \$16 billion in one year. Other savings include the reduction in costs of expensive personal vehicle parking structures, reductions in roadway injuries and fatalities, and savings in road construction and maintenance, police and emergency personnel service costs, and all of the costs that would result from increased sprawl if transit service were reduced.

Transit spending also provides jobs directly through transit system employees who operate and maintain the system's vehicles and facilities and those who administer the system and through employees of companies building transit stations, rights-of-way and other facilities or employees of companies manufacturing transit vehicles. Industries that supply goods and services such as materials and parts for building vehicles, guideways, and stations provide transit-related jobs indirectly. One analysis concluded that transit spending in 2010—\$17.8 billion for capital investment and \$37.8 for operations—supported nearly 2 million jobs.

Technology

Transit managers use transit management computer hardware and software to help them manage the day-to-day operations of the transit system, such as dispatching, service restoration, and service monitoring. A wide range of other technologies aid in managing a transportation network so that it delivers people and goods quickly, efficiently, and safely.

Communications links between transit vehicles and control centers provide information on fare payment, park-and-ride operations, high occupancy vehicle (HOV) and express bus lane access, intermodal communications, and emergency and security information. Geographic information systems (GIS) are computer-based systems that aid transit managers in service and facility planning for routes, assignments, scheduling, ridership, parking lot facilities, shelter locations, running times, accident analysis, and customer complaints.

With an electronic map and a relational database, GIS systems can guide operations using street and route maps, provide emergency call location identification, and make available vandalism

location and history. They can assist in market development by providing information on land uses, employment sites, demographics, and travel patterns. They can simplify customer information and service and analyze service performance statistics and adherence to the Americans with Disabilities Act and HOV violations.

Computer-based vehicle tracking systems, or automatic vehicle location systems (AVL), are one of the most valuable tools in transit management and operations. Used widely in military and emergency vehicle applications, AVL helps transit managers to increase operating efficiency, increase service reliability, improve response to service disruptions, improve detection of mechanical problems, improve driver and passenger safety and security, and various other tasks. Providing accurate information concerning the status and location of transit vehicles to travelers may also improve customer satisfaction and increase ridership. AVL can be a particular boon in providing location information to dispatchers in conducting demand-response routing and scheduling.

Many of these technologies also helped transit systems to respond efficiently to the U.S. Department of Transportation's 2009 initiative, the Mobility Services for All Americans (MSAA), which was designed to improve transportation services and simplify access to employment, health care, education, and other community activities by means of intelligent transportation systems (ITS) technology. The Intelligent Transport System–Joint Program Office under the Federal Highway Administration provided grant money to local communities to help them establish ITS-enabled transportation centers that featured simplified points of access, customer-based travel reservations, and information and trip-planning services. Some of the ITS technologies used included geographic information systems, integrated vehicle dispatching and scheduling, automatic vehicle location, communications systems, electronic payment systems/financial tracking and billing systems, and advanced traveler information systems.

The program helped provide access for older Americans, people with disabilities, and individuals with low incomes to work, school, social activities, and such essential trips as visits to the doctor.

Other technologies serve to make trips more pleasant and more secure for all travelers. Between

2001 and 2011, the number of buses equipped with automated stop announcements increased from 10 percent to 53 percent and buses with exterior bicycle racks increased from 32 percent to 74 percent. Perhaps more significantly, in the same period, the number of buses equipped with closed-circuit security cameras increased from 13 percent to 53 percent.

In the 21st century, transit systems have become more complex to manage and to operate, both technologically and financially. Social and economic changes, a global economy, and increasingly rapid changes in information technology suggest that the future will present greater complexity and more challenges for the transit industry.

Transit Performance Monitoring and Evaluation

Performance measurement is used to some extent in nearly every organization as a tool to monitor how well it is functioning and how well it is meeting its goals and objectives. In the public transit industry, performance monitoring and evaluation can take many forms for different purposes, ranging from internal agency analysis to comprehensive trend analyses or peer review analyses conducted to fulfill requirements of the agency's governing board, local metropolitan planning organization (MPO), or state department of transportation (DOT).

No matter the type of performance evaluation, it is extremely important that the measures used be carefully selected and defined so that the exercise produces meaningful results. Data to compute the selected performance measures can come from a variety of sources, including manual compilation as well as electronic means using the latest technologies. One commonly used standardized data source is the Federal Transit Administration's (FTA's) National Transit Database (NTD). Regardless of the type of performance monitoring or evaluation used, appropriate interpretation and use of the results are critical.

Types

While some performance monitoring exercises may be required by an agency's governing board or other entity, it is still important for agencies to track performance internally. Further, agencies that are recipients of certain FTA grants (Urbanized Area Formula Program §5307 and Other than Urbanized Area Formula Program §5311, specifically) are required by statute to report data to the NTD. From the NTD data collection and reporting process, agencies have a wealth of information that can be used for performance monitoring and evaluation.

Results of performance measurement must be compared with something to be useful. Trend analyses are one way to compare an agency's current performance with its past performance. By examining trends in various measures over time, transit agencies can identify areas in which their performance is improving or not improving. Performance measures

can also be compared against some previously determined target level.

Another way to use performance measures is to compare them among similar agencies as part of a peer review analysis. Such an analysis allows an agency to have an understanding of how its own performance compares against a group of other agencies with similar operating characteristics and environments.

The selection of appropriate peers is a critical element for a meaningful analysis. A Transit Cooperative Research Program (TCRP) report, *A Methodology for Performance Measurement and Peer Comparison in the Public Transportation Industry*, is one source that provides guidance and a method for the selection of peer agencies, as well as a methodology for comparing the peers. In addition to ensuring that suitable peers are selected, the performance measures used in a peer review analysis must be chosen carefully.

For the effort to produce useful results, the measures used must be consistently defined among all the agencies included in the analysis. Data from the NTD are often used in peer review analyses because of the standardized reporting definitions for all agencies; however, other data sources may be used to incorporate other types of measures and information that may not be available in the NTD.

Performance Measures

As already mentioned, the selection of appropriate performance measures is essential for any type of performance evaluation. There are many statistics and measures that can come directly from the NTD or can be computed from NTD data. However, performance measures can originate from other sources, as well, including other databases, the transit agency's own route and schedule information, and demographic or geographic data from the U.S. Census, for example.

Data can be collected manually, such as during a ride check, which is when an individual rides a transit vehicle to count passengers, measure distances, and note travel times. Increasingly, certain types of data are collected electronically using technology such as automatic vehicle location (AVL) systems and automatic passenger counters (APCs). Travel times and distances can be measured using AVL systems, which track the location of transit vehicles using Global Positioning Systems (GPS) technology.

There are several different APC technologies that are used to count passengers as they get on and off transit vehicles along a route, as well as collect other types of data.

From all available data and information, performance measures can be produced. Most measures tend to be developed from the perspective of the transit agency. For example, common performance measures include ridership levels (number of transit passenger trips), number of trips per mile or per hour of transit service, and average transit vehicle speeds.

Common financial measures include cost ratios such as operating cost per passenger trip, per mile of transit service, or per hour of transit service. Another cost ratio, commonly known as the farebox recovery ratio, measures how much of an agency's operating costs are covered by revenues from transit fares. Transit agencies may also be interested in measures of performance related to vehicle maintenance and the frequency of vehicle breakdowns.

Transit agencies are typically interested in other types of performance measures that are also important to the transit passenger, or customer. One measure that has been shown to be of great importance to the transit passenger is the on-time performance of the transit agency's services. Most agencies continually monitor on-time performance, although various agencies may define "on-time" using slightly different thresholds.

Passengers also tend to be concerned about their safety, both while at a transit stop or station and while on the transit vehicle. As such, agencies must pay attention to safety-related measures, both internally and when required to report such measures to external sources such as their state departments of transportation or the NTD.

Transit passengers are also interested in how easy and quick it will be for them to use the agency's services for given trips. Performance measures related to how well an agency's service can meet the trip-making needs of the passengers include the frequency of service (how often the transit vehicles run), the span of service (how many hours in a day the service is available), how easy it is to access the transit stops or stations (are they located where passengers can access them, are the nearby pedestrian facilities adequate, is there parking nearby?), and geographic coverage (do the routes connect passengers' or potential passengers' desired origins and destinations?). *TCRP Report 100, the 2nd*

Edition of the Transit Capacity and Quality of Service Manual, provides a framework for analyzing transit service from the perspective of the transit passenger.

It is important to note that while some performance measures can be applied only at a system-wide level (for example, geographic coverage of the service), most measures can also be applied at the corridor, route, or route-segment level, depending on the type of analysis desired. Analyzing performance by transit route can be an instructive exercise when evaluating an entire system, and it can also be used in determining where service might be reduced when budgetary pressures force agencies to consider providing less service as a way to cut costs.

Challenges

For transit performance monitoring and evaluation, at any level, to provide meaningful results, it is critical that performance measures be selected with great care and with the goal of the effort in mind. It is also necessary that the measures be appropriately defined and that the proper data be available for the measures.

Sometimes, concerns may be raised regarding limitations with large databases such as the NTD. All data have limitations, but the NTD does have standardized definitions and definite reporting requirements. It can be expected that most agencies are reporting those data in the same way, thus making the NTD very useful for performance evaluations including peer review analyses.

Regarding peer review analyses, the selection of appropriate peers has already been emphasized. However, for a peer review being conducted at the request of a governing board or other external entity, an agency may feel pressured to present favorable results and may select peers it knows it can outperform, even if they are not necessarily the best peers. Or, an agency may be told to include a particular transit system as a peer that may be located in a nearby city, or in a city that is often compared to the agency's own city in other ways, even if that particular transit agency were actually a poor peer based on other key characteristics.

Issues such as these further highlight the need to select only appropriate peers. Using a set methodology to select peer agencies can assure governing boards and others of the validity of the peer-review analysis. Further, following a methodology that can

be readily explained to others, for any performance monitoring or evaluation effort, will increase the credibility of the results when shared with others.

When results of performance evaluations or peer review analyses are shared externally, some within a transit agency may express concern about how the information might be used. Similarly, when external groups or organizations use publicly available data to conduct their own performance evaluations, or to compare and rank transit agencies, it can be challenging for an agency to respond, particularly if it seems that the external group did not use appropriate information, or left out pieces of information critical to the agency's performance.

These issues, among others, underscore the importance of recognizing the proper role of transit performance monitoring and evaluation. It must always be remembered that there may be many factors that affect a transit agency's performance that are outside the control of the agency itself. While some performance monitoring systems may be quite comprehensive, many exercises in performance evaluation and, particularly, peer review analysis should be regarded as only one tool out of many to be used in gaining an overall better understanding of a transit agency's performance.

Transit Planning, International

Because land uses generate and attract trips, and the transport system creates nodes of high accessibility (central places) where land uses are concentrated at higher densities, it is logical to plan transport and land use together. This, however, is easier said than done, because land tends to be in private ownership and the transport system in public hands. There is a disconnect, then, between the ownership of transit and most land uses.

If city planners concentrate only on transport or transit planning, there is a real problem of synchronicity. This is particularly true if assumptions are made about what landuse development might take place to justify or support a transit project, and the private landowners fail to deliver the development because, for example, of a downturn in the property market. On the other hand, land development may become a self-reinforcing cycle, creating greater movement demands than the transit project can accommodate.

Transport Objectives

All planning must begin with clear objectives. These are either abstract (for example, improving transit services) or concrete (for example, increasing ridership by 20 percent). From the objectives, a set of policies is prepared to achieve the objectives, and then an action plan is developed to put the policies into practice.

The action plan can be physical (for example, building a new transit line) or administrative (for example, reducing fares or increasing parking charges). Finally, the results of the plan must be monitored to ensure that the objectives are indeed being achieved, without any unintended consequences.

If there is a departure from the desired objectives, then this cycle should be repeated from the

beginning. The problems of restarting the planning process are likely to include the time frames and, less likely, a change in the continuity either of local political control or of the professional staff who were responsible for the first-round plans.

Process

There is an important step that may be required at each stage of the process, namely, public consultation, which can also be used to provide market research information. For public consultation to have merit, it must be undertaken with good will, which means that the transit planners are prepared to modify or even abandon plans as a result of public feedback. If the project is going to be pushed through regardless of public opinion, there has not been consultation, only information on a take-it-or-leave-it basis.

Public Consultation and Involvement

Most countries that are members of the Organization for Economic Co-Operation and Development (OECD) undertake public consultation as a formal part of the planning process. For this process to be productive, the public must be given the information to explain why a plan is required and what the plan is. This information must be intelligible in nontechnical language. Such consultation may benefit from a pilot exercise to ensure that the information is relevant and understandable, and members of the public can make meaningful responses.

This public consultation will use all practical media to make people aware of the process and where and how information can be obtained, if it is not distributed to all households and businesses affected. With the advent of the Internet, and most people having access to it at work and/or at home, most information can be distributed via a dedicated transit plan Web site.

The site can also include a feedback questionnaire, not just on people's views about the project, but also their present travel patterns. As well as recording present travel behavior, this also allows an assessment to be made of people's attitudes toward a new transit service. Attitudes, however, are a notoriously unreliable indicator of future behavior changes.

Demand

Over the last 50 years, the number of trips people make has remained remarkably constant. What has

changed is the average length of those trips and their origins and destinations. Origins have changed as people have moved homes and workplaces.

These changes have taken place because the real cost of travel has fallen. As economists know, demand and price are inter-related; lower prices equal higher demand. Since travel costs have fallen, and people can only make one work trip per day, lower costs have translated into longer journeys. There has also been a major social shift since 50 years ago, when many people lived close to their workplace and went home for lunch.

Therefore, in planning for transit, the number of trips people make is nearly fixed. What is available for change are travel mode, destinations, and times. In the longer term, planners could see changes of origin as some people move to be close to a convenient rapid-transit facility.

Buses, which in many cities provide the largest network of transit services, are often not carrying many passengers. In most cities, bus passengers are considered "captive and with low incomes." They are captive because they have no car or are unable to drive a car. Lower income is a factor because higher-income people without a personal car have other options, such as taxis. Planning for bus services is therefore about serving the maximum number of low-income households, with links to the most frequently used services (for example, business districts, shops, medical facilities, schools, etc.). Such planning will often revolve around cost minimization and service maximization.

In 1992 in Los Angeles, California, the so-called Watts Riots were fundamentally caused by a high level of unemployment in a city with many job vacancies. One of the outcomes of that disturbance was the provision of bus services from Watts to major employment areas. This resulted in a reduction of unemployment. After two years, many of the bus services were withdrawn for lack of demand, because newly employed workers were able to afford cars to travel to work.

Historically, calculating the demand for transit improvements begins by constructing origin-destination (OD) matrices for work journeys, school, leisure, and so forth. Future transit demand is then estimated using diversion curves of the relative attraction of transit compared to a personal car. For the purist, such an analysis is first conducted for present travel to allow the diversion curve model

to be calibrated against the present modal split between cars and transit.

This approach has a number of weaknesses. First, it assumes that present behavior will be unchanged in the future. Second, it assumes that people will hold the same attitude toward a new transit service as they do for the present service. That logic would result in only modest transfers of trips from cars to transit. Forecasts of future transit use have been unreliable in the past, either overly optimistic, with the planned facilities underused, or overly pessimistic, with ridership exceeding forecasts and causing short-term overcrowding, which could prompt some passengers to leave the system. In the medium term, the problem of crowding can be accommodated by careful service management or additional investment in new rolling stock or more stations.

Getting the forecast right is clearly important whenever planners are looking to justify a new investment in transit. Investing additional time at this stage—to undertake further local research on the likely behavior changes or explore similar programs in other cities to get more confidence in the probable demand—planners can make a big difference in the outcome of the project without adding much cost or time.

Competition Between Modes

In most cities, there is little or no competition between modes of travel. The car is “King.” For those people with a car, it is usually the automatic choice.

For transit to create a semblance of competition with the car requires a very special effort and approach. The first stage, as in demand forecasting, is to find out where most car trips originate and are destined. This allows an assessment of those travel flows to be made and the identification of those large enough to be considered economical for a transit service.

The next stage is to find out from present car users the conditions required to attract trips to transit. This should be not only in terms of travel cost comparisons but also in terms of the convenience of accessing the proposed transit service. Few car users will be within walking distance of a new transit stop and some may be within cycling distance, but they will want to use safe cycle paths.

For most, the only practical access to a transit station is by car at a park-and-ride parking lot. The

location of these lots is critical, both to ensure the shortest possible travel time for commuters from door to door, which will be the main comparison used by commuters, but also to cover the costs of providing the service.

Park-and-ride stations need to be near the home end of the journey. Commuters will not usually drive three-quarters of the way and complete the final quarter of the journey by transit, unless congestion or parking are particularly difficult at the destination. Planning for park-and-ride is not always easy, because few people want one next to their backyard.

However, industrial locations present an unattractive place for people to park their cars, unless there are very special measures in place to secure the safety of cars left parked for most of the day and to make people feel safe walking to and from their cars, especially in darkness.

A park-and-ride station typically will be a large parking lot with a small transit station footprint. This provides an opportunity for public art and landscaping to soften what would otherwise be a hard cityscape. Even grass can flourish in many areas of a parking lot, softening the look of the site and making a modest contribution to carbon capture.

Who Is Responsible?

City planning is the responsibility of the city council. Some transit authorities are set up as either autonomous or semi-autonomous from city hall, which can create conflicts of interest and policy. What the transit operator thinks might be good for transit, city hall may view as bad for the city.

So, how can policy and planning be coordinated? It usually comes down not to processes or procedures but to the trust that planners have for the other side. This is intertwined with the ability of both parties to share common goals and then work toward joint objectives. Indeed, each may be able to bring different things to the party, and the sum of the whole can be greater than the parts.

The transit operator will have the responsibility to provide the transit service, the land uses of which may need city hall approval. City hall can bring traffic management, parking controls, and general land use policies that will support transit improvements and encourage transit use. Setting an example is always important in public policy. The mayor and staff using transit themselves is a way to give transit

a big vote of confidence. Citizens will therefore have fewer reasons not to consider transit.

An example of how this can be influential comes from Groningen in the Netherlands, a town of 190,000 people, which by 2000 had seen a major shift in modal split. Car use was 60 percent, bus use 10 percent, and biking and walking made up 30 percent. This was causing major congestion and pollution problems. The city council decided that for health and environmental reasons, car use should be reduced to 30 percent, while bike use would increase to 40 percent and bus ridership to 20 percent.

The first stage in implementing this policy was abolishing free parking for council staff and councilors and putting in more bike parking at city hall. This example and other measures to encourage bike and bus were successful. By 2002, bike use was 55 percent of trips, bus transport rose to 15 percent, and car use dropped to 20 percent of trips. The public opinion of this change has been highly supportive. The benefits include less traffic, congestion, noise, and pollution, along with faster journeys, even on bikes. With more people commuting to work by bike, the health of the population has also improved.

Changing attitudes and behavior can improve the image of transit as well as encourage a modal switch away from car trips. This does not require a financial investment, but it is not necessarily easy, either. The starting point is that those planning the transit improvements believe in them enough to use them for their own travel.

Time Frames

The time frames for transit planning can be as short as six months or as long as 10 years. It took the car industry nearly 50 years to achieve travel dominance, even if auto manufacturers were not always playing fairly. Determining the required time to achieve a planning objective is an objective itself and will depend on the size and scope of the project being planned. The time taken to introduce a dedicated bus lane on a freeway, for example, will be less than what is needed to build a busway or light rail line. The time required to build a subway is much longer still.

The timeline for each planning objective will include public consultation, feedback, plan adjustment, further consultation, and then getting approval. In comparison, the time required for the engineering designs and final construction might be quite short.

Funding and Implementation

Because most transit plans are publicly funded, getting a budget approved can be the most time-consuming part of the planning process. In the political calculus, a dollar spent on transit must be weighed against the value of spending that dollar on schools, libraries, parks, and so forth. Cost is a particularly sensitive issue for transit projects, which tend to cost in the hundreds of millions of dollars, one of the largest single expenditures most local governments will ever plan.

Raising the funds becomes even more difficult when part of the money must come from a central or federal government, which will have additional conditions and regulations and will take much longer to approve. At the federal level, the calculus requires trading off expenditures in City A against City B and so forth.

If a project can be locally funded, it can be done more quickly and with fewer conditions. There are several ways in which this may be possible. In the United States, borrowing money (for example, in a bond issue) will need to be underwritten by additional tax revenue (for example, a sales tax hike). This in turn may require a referendum, which can also be used to provide feedback as part of the public consultation process.

The United Kingdom pioneered the Private Finance Initiative (PFI), where the authority makes a deal with a consortium of companies, including a builder, to construct the required transit facility. The private consortium, then, raises the cash needed on the basis of its financial standing. The transit operator agrees in return to make payments over, typically, a 20-year period, at which time the consortium has been fully repaid its costs and profits, and the operator owns the facility.

There is an interesting twist to PFI, which lawyers and financiers devised. When the consortium initially raises the funds to build the high-risk transit project, the cost of borrowing will also be high, typically 15 percent above the bank rate. The project may take two years or more to build. At that point, there is a concrete asset. The consortium then refinances the project, paying off the high-cost money and replacing it at more usual terms (for example, 4 percent above bank rate). Meanwhile, the transit authority continues to repay the consortium at the terms originally agreed. By this means, the consortium can over 20 years make a 100 percent profit.

Usually, though, the transit operator will either use its own funds or raise a bond issue, and then get contractors and equipment suppliers to bid competitively to build and equip the facility. This process can also have its drawbacks, especially if the transit body lacks the expertise to evaluate the bids, both technically and in financial terms, or to supervise the construction, the cost of which can escalate quickly and dramatically.

Modal Choice and Hierarchy of Modes

For a metropolitan area to have the best transit network will involve a number of different modes operating in a synchronized hierarchy. The planning of such a hierarchy is in some sense like designing a building. The foundations must be right before the walls and roof can be added.

Nevertheless, the benefits of seamless journeys from people's homes to their destinations on one or more modes of transit are both satisfying for the commuter and economically efficient for the community the transit system serves. Offering a fast and frequent transit service, even if it requires changing mode en route, is the most effective way to get car users to switch some of their trips to transit.

Interchanges and Nodal Stations

Planning interchanges and nodal stations can be the most challenging part of the transit planning process, even though all stations are effectively interchanges (for example, between walking and transit). Only those providing interchange between two or more transit lines or modes are discussed. Nodal stations are primary stations because they are serving the Central Business District (CBD), airport or other major traffic generator or attractor.

Finding and securing the land for such stations can be very challenging, even if the transit operator uses compulsory purchase powers, because these facilities can have major impacts on both the community and the political support needed to achieve the project. Getting the land together by private purchase is the most civilized method, unless it leads to "planning blight," which effectively destroys the value of surrounding property and begins a downward spiral of property neglect and dereliction.

The transit authority will wish to be a good neighbor in acquiring property. This will include designing an infrastructure that enhances the local

neighborhood. Indeed, this may be the opportunity to raise civic pride by having a competition of architects to design the new facility and inviting local people to select the one most liked.

Beware, however, that most people cannot read an architect's plans, so the choice will need to be based on a model, which can be physical or a three-dimensional computer-generated graphic. This can show the station's convenience, novelty, and beauty, as well as how it will operate, and help plant seeds for attracting car commuters when it finally opens.

Transit Priority Measures

Transit priority measures are devices employed to improve the travel-time reliability and speed competitiveness of transit services relative to general traffic. Investment in transit priority measures can serve other purposes, including the following:

- Supporting strategic policies, such as urban consolidation, network efficiency,

and environmental management (for example, carbon reduction)

- Improving safety through remediation of conflict points between transit and other modes, particularly pedestrian and cyclist access to transit stops
- Improving passenger comfort through a more direct, less stop-start service
- Delivering better network coverage and integration
- Generating operating and capital cost efficiencies

Plainly, these reasons are not mutually exclusive, and they may singularly or in combination drive an investment decision by transit planning authorities.

Types of Transit Priority Treatment

There are a range of treatments, and these may be grouped according to whether they represent a location-specific point treatment (often at intersections), corridor treatment, or technological investment. The measures are most often applied in locations within an urban road network where there is congestion, with the degree of prioritization dependent on the frequency of bus services and how significant and extensive the congestion is.

By prioritizing transit, authorities may not only reduce service delays and operating costs but leverage more patronage as frustrated drivers identify a relative benefit in using buses. Some priority measures also may only apply at certain times of the day, most commonly during commuter peak travel hours.

Generally, the case for transit prioritization in urban areas across the world is gaining popularity. This reflects the deepening understanding that policy makers have regarding the impacts on productivity associated with traffic congestion and delays. Moreover, there is increasing evidence that congestion cannot be alleviated over the medium and long term through additions to road capacity.

Increasing urban populations and increasing or relatively stable car ownership rates contribute to congestion issues. The need to address the effects of congestion is becoming more evident in developing as well as developed countries, while issues of chronic underinvestment in transit infrastructure in some contexts and its implications become clear. The legacy can include lost productivity, car dependence, and poor air quality.

Overview of Point or Localized Treatments

Typical point treatments include bus queue jump facilities and transit gates or “plugs.” Queue jumps are intended to permit buses to circumvent queues, or lines of traffic, that form at congestion points (typically traffic signal–controlled intersections).

They may also be implemented in partnership with midblock signals to meter traffic and ramp meters at entries to freeways and highways. Queue jumps are effective only if they are of sufficient length to permit a congestion point to be bypassed; if general traffic queues frequently extend back past the entry to the bypass lane, they become ineffective.

On approach to intersections, physical barriers do not usually separate queue jump lanes from adjacent traffic lanes. This is because it is often desirable or a legal requirement to permit turning traffic to enter the queue jump lane, but only a short distance from where a cross street or crossover is located. At intersections, queue jump facilities can be established as either curbside or median lanes, depending on the direction in which transit services need to travel.

Physical barriers can be more appropriate on ramps and midblock, where intrusions by general traffic may need to be avoided. Transit gates are used to help control access to these kinds of midblock facilities and may also control access to corridor treatments. Using intelligent transport systems (ITS), such as Global Positioning System (GPS) transponders on buses, gates may be raised only when a bus fitted with the technology onboard actuates the activity. At other times, traffic is precluded from entry.

In Europe, “sump busters” (a solid mass designed to destroy the oil pan of any vehicle with an insufficient ground clearance to avoid the obstacle) are sometimes incorporated as point treatments at entries to bus-only facilities, because buses have sufficient axle width to pass over them.

Transit plugs are short links that permit buses, but not general traffic, to cross a reserve or other land area and thus avoid a circuitous detour. Transit plugs often demonstrate a compromise between bus operating requirements and a desire to preserve the integrity of the land use that the infrastructure crosses; that is why the exclusion of general traffic is desirable.

Transit malls are similar to transit plugs insofar as they serve as a transit-only link between two road corridors. However, they have a critical land

use component that transit plugs do not. Transit malls are generally lined by building development with retail premises on the ground floor. The transit service helps activate the land use by supporting pedestrian activity, and transit stops within the mall are an important element of the treatment. The Bourke Street Mall in Melbourne, Australia, provides a good light rail–based example.

Overview of Corridor Treatments

Corridor treatments include transit-priority lanes. These can be fully exclusive, partially exclusive, or nonexclusive. Fully exclusive lanes represent the most aggressive road-based transit solution and generally require the highest level of investment. They are, therefore, adopted as the preferred treatment for trunk routes where there is significant patronage. These lanes need to be physically separated from general traffic, and entry to the lanes should be managed through use of actuated barriers or similar. While they can deliver the greatest amount of transit service reliability and support high operating speeds because of the reduced risk of conflict with other modes, they can be physically divisive phenomena within the urban fabric.

The TransMilenio system in Bogotá, Colombia, is one of the most famous exclusive bus rapid transit (BRT) systems in the world. The busiest corridor within the system (Caracas) carries upward of 45,000 passengers per day, and the operating profile of the system requires facilities at some stops to permit overtaking (passing). TransMilenio has significant at-grade operations, which affects cross-corridor movements by other modes of transport.

In Brisbane, Australia, the BRT system has a significant grade-separated component to alleviate some of the movement restrictions for other modes. However, this has come at considerable capital cost.

Partially exclusive and nonexclusive transit lanes may be provided either curbside or in the median of road corridors. Partially exclusive lanes may have intermittent physical barriers—crossing movements may only be permitted at intersections—whereas nonexclusive lanes may only be differentiated from standard pavement by a particular color treatment (for example, red or green).

Nonexclusive lanes tend to be intruded by general traffic most frequently, with consequential impacts on the reliability and operating speed of transit services. They are a comparatively cheap

An example of a bus queue jump lane on approach to a signalized intersection along Great Eastern Highway in Perth in western Australia. At intersections, queue jump facilities can be established as either curbside or median lanes.

corridor treatment and best suit corridors where there is a need to retain opportunities for frequent cross movements. Given a lack of physical separation between bus and general traffic lanes, monitoring and enforcement can become important. This may be undertaken practically through use of closed-circuit television (CCTV). Through application of dynamic signage/ ITS, partially and nonexclusive lanes can operate with contra flow or only during peak periods.

Overview of ITS Treatments

There are a range of ITS solutions associated with traffic signal control along transit routes. These measures represent the third of the three main groups of priority measures, along with the point and corridor treatments. Passive signal priority systems do not have to be actuated by transit vehicles. They occur automatically during designated periods. Passive systems may therefore be

This transit plug allows traffic to pass through public open space in the suburb of Kardinya in Perth, Australia. Transit plugs may be enforced through closed-circuit television monitoring.

criticized for generating inefficiencies, because they can reduce the level of service for general traffic whether or not transit vehicles are benefiting.

Passive systems include the following:

- Transit-signal timing, which has to be coordinated carefully with transit timetables and may not work effectively if services experience delays upstream and do not arrive at intersections when expected
- Priority movement repetition (for example, multiple phases favoring transit within one signal cycle), which reduces incidences of delays for transit vehicles
- Green priority weighting (for example, longer green-light phase time for transit vehicle movements)
- Reduced cycle time, which is useful for transit if services approach on minor

legs at intersections, because the applicable green signal phase will occur more frequently

In contrast to passive systems, actuated systems have to be “called up” by approaching transit vehicles through application of onboard GPS transponders or travel across detector loops. The relative benefit of actuated systems is that they are demand responsive and can therefore reduce inefficiencies within the broader traffic system. The second and third benefits are the reliability that the transit service will arrive at an intersection at the right time to benefit from the priority treatment and the opportunity to compensate for increased green time for transit between actuated phases, respectively.

Actuated systems include the following:

- Green light pre-emption (for example, green phase call up)
- Green phase extension
- Multisignal linking along a corridor (although this can be complicated by the location of intermediary stops), creating a green wave

ITS solutions can be set up to apply only during peak hours. This may be suitable on networks that exhibit “high tide” congestion (that is, pronounced peaks and long inter-peak troughs). Typically, peaks occur in the mid-morning and late afternoon as a function of commuter travel. In many cases, peak traffic flows are in one direction—hence, the idea of tidal flow—based on the agglomeration of jobs in one location (for example, a central business district) and residences elsewhere.

Some physical point and corridor treatments can also be effective as peak hour transit priority devices, such as the curbside bus priority lanes.

During the intra-peak, signage and thermoplastic stenciling on the road surface inform general traffic that the lanes are for buses only. Outside of these times, general traffic can use the lanes and, in some instances, curbside parking is permitted. In some cities, similar lanes are provided in the median with the direction of flow for transit reversing depending on the peak direction of traffic. Time-based exclusivity becomes infeasible when physical separation is incorporated in priority treatments.

Selection of Priority Treatment

Policy makers and planners will generally go through a set of criteria to select the appropriate transit priority measure for a given geography. Plainly, the selection process will be influenced by the extent of congestion on the existing road network, service travel times, expected growth in travel demand, and budget implications. However, other pertinent considerations include the following:

- Number of services affected per hour in each direction
- Patronage for each service and overall during the period of interest
- Constructability of physical measures, which is affected by existing road geometries, frequencies of road crossings and crossovers, reserve widths, and servicing infrastructure
- The potential efficacy of a treatment (that is, what are potential, quantifiable benefits?)
- Hardware and software requirements (where ITS is involved)
- Social and political acceptance

Some transit authorities, such as the Public Transport Authority of Western Australia, have established guidance patronage thresholds for helping decide cases for investment in corridor-based exclusive bus infrastructure as compared to very localized or semi-exclusive priority facilities. These thresholds may also be considered based on overall corridor capacity. For example, bus lanes along very busy routes can carry more people than a general traffic lane. Within such a context, if latent demand for prioritized transit services is high, reallocation of traffic lanes can be warranted.

While it is generally accepted that investment decisions should be made on a case by case basis, there is still an expectation that there is strong justification for whatever treatment is specified. Often, multi-criteria analysis comparing various treatments with a business-as-usual scenario is necessary. Typically, this will incorporate traffic analysis that considers both impacts on transit and general traffic. The latter can be impacted by variables including the following:

- Transference of road space from general vehicles to buses

- Allocation of green time at traffic signals to bus-only phases or phases that support bus movements
- Reduced network connectivity and lot access created by physical barriers to entry to bus lanes

Otherwise, transit service philosophies can exert a strong influence. These can range from treating transit as a basic social good, and therefore only minimal investments are supported, through to a city forming tool and strong alternative to private vehicle travel. In the latter case, transit priority measures may be implemented aggressively to provide transit services with a strong competitive advantage over general traffic, even on secondary (that is, nontrunk) routes.

Increasingly, authorities also need to be aware of the costs of not investing in sufficient transit priority, which can include added costs—economic, environmental, and economic—associated with congestion and unintended impacts on urban form.

Transit Ridership

During the 19th century, changes in public transport technology shaped transit affordability and ridership in the United States. In the 1820s and 1830s, only wealthy individuals could afford to ride the first type of public transport in U.S. cities—horse-drawn rectangular boxes on wheels called omnibuses. Steam railroads, initially introduced in the 1830s, were able to lower operating costs over time and by the middle of the 19th century became affordable for the middle class for commutes from the suburbs to the city center.

The horse-drawn railcar—essentially a horse-drawn omnibus on rails—and later the electric streetcar made urban transit within cities affordable for all but the poorest. Replacement of streetcars with motorbuses began in the early 1900s. Overall, public transport in the United States experienced a steady growth in passengers until the 1920s, when ridership declined during the Great Depression that saw high unemployment and bankruptcy of transit systems.

After initial declines in patronage during the 1920s and 1930s, public transport ridership surged during World War II. Public transport reached its peak ridership with about 16 million passengers per year during that time. The rise in transit use during the war was fostered by wartime fuel and tire rationing and the use of automobile factories to construct military vehicles instead of automobiles.

The decline of transit demand that had started in the 1920s and 1930s was only interrupted during World War II, however. After the end of the war, in the face of rapid suburbanization and skyrocketing automobile ownership, demand for public transport in the United States fell sharply, from 16 billion passengers per year in 1945 to 5 billion passengers per year in 1973. Moreover, in many parts of the country, public transport, and especially buses, became the mode of transport of last resort. Ridership was often limited to those who could not afford an automobile.

Since the 1970s, public transport demand has increased steadily and reached 7 billion passengers per year in 2010. Fluctuations in public transport ridership between 1973 and 2010 were related to economic cycles and gasoline prices, with higher levels of ridership during economic booms and periods with higher prices for gasoline.

In 2010, Americans made about 25 trips by public transport per year. This compares with much higher levels of transit ridership in Switzerland (237 trips per year), Germany (139), Sweden (139), the United Kingdom (116), Belgium (100), Norway (96), France (87), Spain (78), Finland (73), Italy (65), and the Netherlands (51). Even Canadians, America's neighbors to the north, made twice as many transit trips per year (51).

In spite of increasing total ridership annually, public transport in the United States has not increased in terms of share of trips, because of a still growing number of trips by automobile. As a result, since the 1970s, public transport in the United States has accounted for roughly 2 percent of all trips.

By contrast, public transport's market share in Europe is much higher, reaching 10 percent in countries such as Germany, Sweden, Great Britain, and Norway, and 5 percent to 10 percent in the Netherlands, Finland, Denmark, and France. In Switzerland, over 20 percent of all trips are by public transport. In Canada and Australia, public transport accounts for 1.5 to two times higher shares of regular commuters than in the United States. Trends are also more favorable in European countries and Canada, where public transport has increased its share of all trips over the last two decades.

In all countries, the demand for public transport varies by demographic and socioeconomic characteristics, trip purpose, mode of public transport, and land use. In this article, these trends are highlighted for the United States, with occasional references to European countries, such as Germany, to highlight unique aspects of public transport in the United States.

Rail Versus Bus and Trip Purpose

In the United States, the majority of public transport trips (roughly 70 percent) are by bus. Rail only accounts for 30 percent of public transport trips. In European countries, public transport demand is more equally split between bus and rail modes—often with a slightly higher share of trips by rail than by bus. For example, in Germany, 57 percent of transit trips were by rail in 2009 (compared to 43 percent by bus).

Public transport demand in the United States is dominated by commute trips to work, which account for about 40 percent of all transit trips, followed by personal business (32 percent), social/

recreational (20 percent), and educational (12 percent) trip purposes. In western Europe, the commute is less important for public transport demand, because public transport is a viable option for many trip purposes and at all times of day.

In some countries, trips for educational purposes account for a high share of transit trips. For example, in Germany, commute trips to work accounted for 24 percent of transit trips and trips to and from school made up 25 percent of transit trips. In European countries, such as Germany, school children often ride public transport to and from school.

In the United States, school systems typically have their own fleets of school buses. In 2010, there were five times as many school buses as public transport buses in the United States. However, school buses are not considered public transport, because school buses are used only by school children and are not open to the public.

Rider Demographics

Women ride public transport at a higher rate than men in the United States: 2 percent of trips by women versus 1.8 percent of trips by men. The 16-to-24-year-old age group has the highest share of trips by public transport (3.1 percent), followed by 25 to 44 year olds (2.1 percent). Public transport ridership is lowest for those between age 5 and 15 (1.1 percent of trips) and those older than 65 years (1.4 percent of trips). In western European countries, such as Germany, women also ride transit more than men (8.8 percent versus 8.2 percent of trips).

However, transit ridership does not fall with age in Europe. For example, in Germany, public transport accounts for 8 percent of trips by those 65 and older, compared to only 5.5 percent for those between 45 and 64. Overall, public transport ridership is higher for all groups in Europe.

In the United States, racial and ethnic minorities—particularly African Americans—use public transport at a higher rate. In 2009, African Americans accounted for only 12 percent of the U.S. population but 32 percent of all transit riders. By contrast, whites accounted for 73 percent of the population but only 39 percent of transit riders.

Socioeconomics

Public transport ridership falls with increasing automobile ownership and incomes. In fact, in 2009, public transport in the United States accounted for

21.6 percent of trips for individuals who did not own a car, but less than 1 percent of trips in households that had more cars than licensed drivers. The group of individuals that do not own a car can be divided into at least two subgroups: those who do not wish to own a car and those who cannot afford to own an automobile but would like to own one. Both groups depend on public transport for a high share of trips.

Individuals in the lowest income quartile made 4.1 percent of their trips by public transport compared to only 1.1 percent of trips by public transport for individuals in the highest income quartile. Incomes of public transport riders also differ by mode of public transport. In 2009, bus passengers had a median household income that was only one-third of the median household income of rail passengers (\$22,500 versus \$ 65,000).

In fact, median household income of rail passengers was higher than the national average (\$50,000). Part of this is explained by the concentration of commuter rail systems and subways extending to high-income suburbs surrounding San Francisco, California; Washington, D.C.; Chicago, Illinois; and New York City. Buses, by contrast, serve poorer inner-city neighborhoods and are often stigmatized as a transport option of last resort.

In European countries, such as Germany, incomes of bus and rail passengers are comparable to national median incomes. Moreover, public transport attracts a higher share of trips from high-income individuals and those in households with more cars than drivers, which make 8.4 percent and 5.7 percent of their trips by public transport, respectively.

Land Use and Spatial Distribution

In the United States, public transport ridership is concentrated in large metropolitan areas. In 2010, the New York City metropolitan area accounted for 40 percent of all transit trips in the United States. Combined, the Boston, Chicago, Los Angeles, New York, Philadelphia, San Francisco, and Washington, D.C., metropolitan areas accounted for roughly 70 percent of all trips by public transport in the United States.

Moreover, public transport ridership is highest in higher-density areas. In 2009, public transport accounted for 11 percent of all trips in areas with a population density of more than 4,000 people per square kilometer (3.86 miles). Conversely, only 0.3 percent of trips were by public transport in areas

with population densities of less than 300 people per square kilometer.

Public transport use is also more common in larger metropolitan areas. Transit accounted for 2.9 percent of trips in urbanized areas larger than 500,000 inhabitants, compared to only 0.2 percent of trips in rural areas. Transit ridership also varies by region of the country. In 2010, the transit share of trips was 5.1 percent in the northeast census region, 2 percent in the west, 1.2 percent in the midwest, and 1 percent in the south.

In European countries, public transport ridership is more equally distributed across cities and other parts of the country. For example, even small towns, such as Freiburg, Germany, have ridership levels of 18 percent and higher. Similarly, the difference in the transit share of trips between German states ranged from a low of 6.3 percent in Lower Saxony to a high of 8.9 percent in the state of Hessen.

In 2009, public transport accounted for 5.9 percent of all trips in rural areas in Germany, and 17.7 percent of trips in urbanized areas with more than 500,000 inhabitants. German public transport also attracted 6.1 percent of trips in low-density areas (fewer than 300 people per square kilometer). In high-density areas (that is, 4,000 people per square kilometer), 16.2 percent of trips were made by public transport.

Policies to Increase Ridership

Higher levels of public transport ridership for all groups in Germany than in the United States can be explained by several factors. First, compared to the United States, Germany has more and higher-quality public transport services. Second, in Germany, most transit agencies offer steeply discounted monthly and annual tickets that attract regular riders.

Third, regionwide coordination of transit services and fares in Germany allows passengers to conveniently change between rail and bus transit and across operators with one ticket. Fourth, gasoline taxes, traffic calming, strict speed limits, parking restrictions, and fees for car parking make car use more expensive and slower in German cities.

Finally, land use policies in Germany discourage low-density and single-use suburban sprawl and foster dense and mixed-use developments that can be effectively served by public transport. In the United States, there are some successful examples, such as the Rosslyn-Ballston Corridor in Arlington,

Virginia, that demonstrate that mixed land uses and high population densities can help promote public transport in suburban areas.

Transit Safety

Public transit, including buses, commuter trains, light rail, and subways, is a generally safe mode of transportation, particularly when compared to driving in private cars. Although public transit systems have the potential to act as crime magnets, bringing together large numbers of people into relatively confined areas, transit areas (for example, buses, trains, and stations) are as safe as, or safer than, the corresponding city streets.

Various approaches have been taken to reducing both transit crime and the perception of crime on

transit, including increasing police presence, maintaining a clean and orderly environment, enforcing regulations strictly, and prosecuting even minor crimes (a “zero-tolerance” approach).

Bus Accidents

In the United States and many other countries, bus travel is relatively safe, and serious accidents are rare. According to the Fatality Analysis Reporting System (FARS), which contains information about fatal traffic crashes in the United States and Puerto Rico, there were 43,945 fatal traffic accidents in the United States and Puerto Rico in 2011, of which 535 (1.2 percent) involved a bus; the preponderance of fatal accidents involved either passenger cars (39.7 percent) or light trucks (37.2 percent).

In the same year, there were more than 2.7 million accidents causing injury, of which 6,000, or 0.2 percent, involved a bus. Of the 6,612,000 accidents causing property damage in 2011, only 7,000 (0.1 percent) involved a bus. Of 27,060 vehicle occupants killed in traffic accidents in 2011, only 54 were bus passengers, and of the 2,091,000 vehicle passengers injured in traffic accidents in 2011, about 13,000 were bus passengers.

The Transit Cooperative Research Program of the U.S. Transportation Research Board identified a number of practices that are associated with accident prevention in bus operations. In the area of human resources, these practices include screening potential drivers through structured interviews and work sample tests, as well as a review of their driving records and prior employment histories. Also included were providing defensive-driving training, offering incentives for maintaining a clean driving record, and educating passengers, including school children, in safe riding practices.

Management activities associated with greater safety include tracking and analyzing accidents, educating the public, identifying hazards, performing safety inspections, and supervising drivers. Operations activities associated with increased safety include locating bus stops with traffic patterns in mind, removing snow and ice during inclement weather, enforcing traffic and parking laws, and using unidentified observers and surveillance video technology on buses.

A researcher investigating data from intra-city bus routes in Uppsala, Sweden, found that several factors were related to the occurrence of bus

accidents. As is true with driving accidents in general, traffic density was strongly related to accident occurrence, with the morning and evening rush hours being the most likely times for accidents to occur. The influence of heat and rain on bus accident rates was also investigated, but no evidence was found that either condition was significantly related to the occurrence of accidents, in contradiction to what some other researchers had found.

Bus Crime

Minor crimes, including theft and robbery, are typical crimes committed on buses, while violent crimes are less common. Crimes often reflect typical patterns of crime in a given city, as well as general societal factors. For instance, the increasing prevalence of electronic devices such as smartphones, which make promising targets for thieves, has been blamed for a 42 percent increase in thefts on Chicago Transit Authority (CTA) buses and trains from 2009 to 2011.

Opportunity is also a factor. For instance, New York City experienced a surge of robberies of bus drivers in 1968 and 1969, a problem that was almost completely eliminated when drivers stopped making change (and thus did not carry money).

Bus hijackings and hostage incidents are rare occurrences but generally receive wide publicity, hence, they loom larger in the public mind than their statistical occurrence would suggest.

One of the most famous bus hostage incidents took place on June 12, 2000, in Rio de Janeiro, Brazil, and was the subject of the 2002 documentary film, *Bus 174*. In this incident, Sandro Rosa de Nascimento, a former street child, boarded city bus #174, intending to rob the passengers. However, one of the passengers saw that Nascimento was armed and signaled the police, who intercepted the bus.

It became a hostage situation, with large numbers of police and members of the media surrounding the bus, and Nascimento communicating with messages written on the bus windows and shouted out the windows. He let some of the passengers go, but used others as human shields, and faked the execution of one of them. In the early evening, he left the bus, holding one of the passengers before him as a human shield. This hostage, Geisa Firmo Gonçalves, was killed by a combination of bullets fired by Nascimento and the police (she was the only passenger

to die in the incident), while the other passengers were essentially unharmed. Nascimento died from suffocation while in police custody.

Another major hostage crisis occurred in the Philippines on August 23, 2010. A former police officer, Rolando Mendoza, boarded a tourist bus carrying 25 people, mostly from Hong Kong, in the Rizal Park area of Manila. He displayed weapons including a handgun and an automatic rifle and demanded that city officials restore him to his position on the police force. The hostage crisis became a media event, and Mendoza became agitated after seeing this coverage on the onboard television.

After he began killing the passengers, a SWAT team forced its way onto the bus, but the process took about an hour, due in part to the Plexiglass safety windows and the fact that the door could not be forced open. Eventually, Mendoza was shot and killed, but eight bus passengers were also killed during the incident. Investigations by both the Filipino and Hong Kong governments faulted the Filipino police handling of the incident.

Although passenger assault on buses is a rare occurrence in most countries, some serious incidents have drawn public attention to the problem and suggest that they may be more common in the future than previously believed. One such incident was the 2012 gang rape of a woman on a bus in New Delhi, India; her male companion was tied up and beaten until he was unconscious.

The woman later died from her injuries, and the six men who took part in the assault were all charged with murder; one of the assailants, who was also the bus driver, hanged himself in jail. This crime sparked protests across India and drew attention to alleged problems with police corruption and the apparent lack of concern with prosecuting rape cases or otherwise protecting women from sexual assault.

Following the widespread publicity from the New Delhi rape and murder, several sexual assaults on public transportation in Rio de Janeiro, Brazil, also came to public notice. One involved a woman who was raped by an armed assailant on a bus full of passengers, while the driver continued to drive the bus on its normal route.

Another involved a woman who was raped and abducted on a transit van while it drove through densely-populated parts of the city. The perpetrators of the latter crime were not prosecuted

by police, and the same men, using the same van, are accused of repeating their crime a week later, assaulting and raping a 21-year-old female American student and assaulting her male companion.

These crimes drew attention not only to problems with passenger safety but also with a police department and justice system that some charge is unconcerned with assaults on women, and with crimes perpetrated on working-class and poor people. Following the rape of the American student, private transit vans were banned in the southern part of Rio de Janeiro, which is also the most prosperous part of the city, and vans were prohibited from using tinted windows (to make it more difficult to conceal crimes within).

Rail and Subway Accidents and Suicides

In general, rail travel is a safe mode of travel in the United States and other industrialized countries. For instance, in 2007, there were about 43,000 transportation-related fatalities in the United States, and 188 occurred on rail travel, with 124 occurring on commuter-rail operations and another 32 on light rail operations. This comes to about 30 fatalities per 1 million passenger trips for commuter rail, and 8 per 100 million passenger trips for light rail.

Suicides and accidental deaths are far more common on the New York City subway system than homicides, although the latter usually draw more publicity. During a four-and-a-half-year period—2003 to 2007—there were 211 fatalities in the New York City subway system; of these, 111 (52 percent) were suicides, 76 (36 percent) accidental deaths, four (2 percent) homicides, and 20 (9 percent) of undetermined cause.

The most common cause of death was blunt trauma (206; 98 percent), with the remaining five deaths caused by electrocution. The most common cause of accidental death was trespassing on the rail bed or falling onto the subway tracks; a few were caused by falling between trains, by “train surfing” (riding on the roof of a train), or “skylarking” (riding outside the train, hanging onto the doors).

The average age of a person dying in the subway system was 44 years, and 83 percent of those dying in the system were male. Racial and ethnic makeup of the dead was similar to that of New York City as a whole, with 32 percent white, 28 percent Hispanic, 28 percent African American, and 11 percent Asian.

Post-mortem examinations found high rates of alcohol (42 percent) and cocaine (25 percent) in the bodies of those who died accidentally, and somewhat lower rates of antidepressants (21 percent) and alcohol (14 percent) in those who died by suicide. Most suicides occurred during the morning rush hour (6:30 A.M. to 9:30 A.M.), while most accidental deaths occurred between 4:00 A.M. and the morning rush hour.

A 2007 report by the Metropolitan Transit Authority (MTA) on worker death in the New York City subway system revealed that 238 workers had been killed in subway accidents between 1946 and 2007, with half of those occurring before 1960. The most common cause of worker death was being hit by a train while working on the roadbed; other causes included electrocution, fatal injuries in a collision, and being shot during a robbery.

The worst accident in the New York City subway system in 63 years took place on August 28, 1991, resulting in five passenger deaths and over 200 injuries. The cause of the accident was a derailment near the Union Square Station in southern Manhattan caused by excessive speed (over 40 miles per hour in a 10 mph zone). The motorman (who controls the train's speed and braking), Robert Ray, did not report immediately for alcohol testing, but 13 hours later had 0.21 percent alcohol in his blood, far over the legal limit.

Ray later claimed that he fell asleep just before the crash, and he was sentenced to 15 years in prison, of which he served 10 years. The safety equipment in the area where the crash occurred, a system of switch points and trip arms that measure a train's speed and activate the emergency brakes automatically, was found to be working at the time of the accident, but the train was moving too fast to be stopped in time.

Subway Crime

Most subway crimes are minor, including theft, and often reflect the general crime rates in the city where the subway is located and/or the neighborhood in which a particular stop is located. In fact, subway stations are often safer than the streets because of the relatively large numbers of police assigned to patrol them.

Despite these facts, fear of crime in subway stations and on trains seems to be greater than among people who use surface transportation, particularly among women, perhaps because of

A number 7 train pulls up to a platform in New York City. From 2003 to 2007, there were 211 fatalities in the New York City subway system, with 98 percent caused by blunt trauma. The average age of a person dying in the subway system was 44 years, and 83 percent were male.

the enclosed nature of the subway system and the perceived difficulty of escaping from an attacker. Crime in stations is more common than crime on the trains themselves.

The New York City subway system was widely perceived as a dangerous place in the early 1960s, and evidence of increasing crime led then mayor Robert F. Wagner to more than double the number of members of the Transit Police Force from 1,219 to over 3,100. Transit officers were assigned to patrol every station in the system in the evening and early morning hours.

A 1974 analysis by the New York City Rand Institute found that both minor and serious crimes decreased during the hours of patrol, and that crimes also decreased over the other hours of the day as well. In other words, rather than crime being displaced, it was reduced over the entire day. When the special patrols ended, crime did increase, but primarily during the hours that were never included

in the special patrols, with most crime occurring between 4 A.M. and 8 P.M. It is noteworthy that those hours also see much of the ridership, and hence more potential victims are available.

In the 1980s, the subway system was again perceived as dangerous, with public fear and anger focused by the highly publicized case of Bernard Goetz, the so-called subway vigilante. Goetz shot four muggers on a subway train in 1984 and was only convicted of illegal possession of a firearm; some viewed him as a hero for standing up to criminals at a time when the police seemed unwilling or unable to control crime.

One approach by the Transit Authority to reduce crime was a campaign to remove graffiti from all trains, following the “broken windows” theory that the appearance of disorder encourages more crime. Transit police also began a zero-tolerance approach by cracking down on minor offenses such as fare evasion on the theory that people committing such crimes might also be wanted for more serious offenses. Crime did decline by the early 1990s, although the specific reasons for this decline remain unclear because crime declined across the city as a whole in the same years.

Assault and Harassment

In contrast to minor crimes like theft, the most highly publicized incidents in the subway system are usually injuries and deaths to passengers, which are relatively rare occurrences, particularly given the number of people who regularly use the subway (over 4 million daily in New York City, for instance).

In 1999, two separate incidents involving mentally ill people who pushed people from the platform onto the tracks motivated passage of a law allowing New York State to order individuals into involuntary outpatient psychiatric commitment. The involuntary commitment law is called Kendra’s Law in honor of one of those two victims, Kendra Webdale, who died after being shoved in front of a train by Andrew Goldstein, a diagnosed schizophrenic who was not following his prescribed course of treatment. The second victim was Edgar Rivera, who lost both legs (but survived) after being pushed in front of a train by Julio Perez, a homeless man who was schizophrenic.

Sexual harassment, including groping, is a known problem on some subway systems, where crowded cars and the anonymity of the passengers

provide the opportunity for such crimes and may make it difficult for victims to get away or even to identify their assailant. It is difficult to know how frequent the problem is, because many cases are not reported, but it is believed that most victims are female and most assailants male.

In Japan, public groping is known as *chikan*, and due to the perceived extent of the problem, women-only cars have been introduced in some cities. In Egypt, sexual harassment of females is called “Eve teasing,” although some object to that term because it implies that the harassment is mild (“teasing”) or that the women themselves are responsible (in the Jewish and Christian Bibles, Eve tempted Adam to disobey God).

Some cities, including Mumbai in India, now offer women-only compartments on trains in an attempt to shield women from harassment. Other countries with women-only railcars or buses include Mexico, Indonesia, Taiwan, and Israel, although the motivation in Israel is less to reduce crime than to observe customs of separating genders among Orthodox Jews.

Transit System Technology

Transit system technology is the sum of all historical, contemporary, experimental, and theoretical tools that embody some degree of utility for the planning, developing, constructing, operating, monitoring, upgrading, funding, and administering of transit networks. This technology includes such capital-intensive aspects as train engines and rolling stock, switching yards and dispatcher communications installations, people-mover devices at airports—in short, the vehicles, buildings, and right-of-way improvements that form the physical modes of transit.

The technology also includes such potentially capital-conserving aspects as decision-making software, operations budgeting templates, passenger information display devices, and other information-based, cybernetic, and wireless systems.

Technology Integration

A major force driving the shaping of policy solutions to transit system problems today is the concept of a coordinated methodology and application set, continental in scope, that provides a consistent and economically efficient guide to the infrastructure and operational systems of mass transportation. By standardizing transit system technology and its administration, by incentivizing wise policy implementation, and by funding research and application of more efficient technologies, such programs can lead to the adoption of smarter systems by a growing number of municipalities and regions.

Through the Intelligent Transportation Systems Joint Program Office of the U.S. Department of Transportation (DOT)'s Research and Innovative Technology Administration (RITA), for example, challenges such as corridor congestion and intermodal exchange are receiving some of the first directed attention and research funding. RITA directives such as its Integrated Corridor Management (ICM) program are slated to translate from research into better-planned and more effectively operated metropolitan and regional transit systems.

One element illustrative of the ICM approach is the Clarus initiative, by which extensive real-time weather reporting and forecasting data is compiled, sorted, and categorically ramified, the results being disseminated to users with diverse needs across the transit spectrum. Five components of Clarus show how the results can serve different user bases that together ease congestion and reduce hazards across a given transit system:

1. Enhanced road weather forecasting for all surface transit modes
2. Seasonal weight restriction decision-support tool for trucking and rail
3. Nonwinter maintenance and operations timing support
4. Multistate surface mode control strategy support
5. Enhanced road weather content for travel advisories

As a result of testing and tuning of the Clarus system in the 13 U.S. states and three Canadian provinces that began in 2004, the U.S. Federal Highway Administration (FHWA) identified specific means

“to foster collaboration between transportation engineering, computer science, and atmospheric science disciplines” toward the goal of using data to improve transit operations management and create innovative interfaces within and between transit agencies.

FHWA then awarded eight contracts as of 2011 for the development of data integration, visualization tool improvement, alert system upgrades, mobile applications, and related technologies. These applications are coming online for use by trucking companies, bus systems, urban and rural motorists, emergency response and police departments, road crew managers, transit system operations centers, insurance companies, and other user bases in the United States and Canada.

Specific to congestion problems, the ICM system combines and connects data and management tools across four major areas of transit: rail systems, bus systems, freeway systems, and arterial signal systems. The research approach is to develop both information and hard infrastructure technology that together can yield a better informed, time-sensitive, and conditions-predictive operations management and user base across all modes in a given transit corridor that has been identified for comprehensive improvement.

The ICM policy and its successful adaptations to local realities depend upon the active participation of the diverse parties involved, such as local jurisdiction agencies that operate traffic signal systems, regional rail agencies operating train management systems, state transportation bodies managing flexible freeway access and traffic flow, and bus companies utilizing automatic vehicle location systems. Technology transfer among such parties is facilitated by their dedicated engagement within a regional ICM working group, partly funded under federal auspices via the FHWA and sister agencies.

ICM embodies a full catalog of management and operational standards for each transit mode and for the real-time exchange of data between the agencies monitoring and controlling each mode. The standards continue to develop under the guidance of such bodies as the Institute of Transportation Engineers, the American Public Transportation Association, and similar groups. The ICM standards embody aspects as diverse as data sharing protocols, signal and sensor device metering, and signal control prioritization.

ICM further utilizes ongoing improvements in data gathering, display technologies, electronic credentialing, targeted automated screenings, and intermodal data sharing in order to advance both passenger and freight transport management. The freight area in particular involves even more modes of transit, with its focus on multimodal exchange, international border operations, maritime applications, and commercial vehicle information systems and networks that are available to both private and public users.

Intelligent Transit

Ideally, the heavy infrastructure and the information components of a transit system work together to form what is called an intelligent transportation system (ITS). One such system that today exists in a status somewhere between the theoretical and the widely practical is the connected vehicle environment. There are numerous large interested parties—from the federal government’s DOT to private concerns including Google, Inc.—that are committing significant resources to research and develop this type of intelligent transportation system.

As envisioned, it will comprise private and public motor vehicles linked via wireless communications to a hybrid centralized-distributed monitoring and control system that provides safe and secure remote-assisted guidance and vehicle spacing during normal operations on designated public roadways. (This is not a “driverless car” scenario, but it does incorporate some aspects of driverless technology.)

It is conceived that the connected vehicle environment will deliver benefits including enhanced driver and passenger safety, greatly increased roadway capacity, reduced congestion, significant fuel and energy savings, cleaner environmental conditions, and household economy savings, as well as job growth through automotive and telecommunications industry expansion, related intermodal transit improvement, and streamlined regulatory functions.

On the government’s part, the research into this mode of transit is being spearheaded and coordinated by RITA. Mandating that the system be “national in scale and extensible across North America,” RITA is particularly dedicated to safeguarding the leading priority of all DOT programs—safety.

Yet, in the working statement of purpose for this project, RITA notes that other uses of a connected

vehicle environment, “especially for mobility and environmental purposes, are permissible and encouraged as long as they do not detract from safety.”

RITA documentation also notes that the connected vehicle environment must use dedicated short-range communications (DSRC) technology unless or until an equivalent system is devised that tests to be at least as safe as DSRC. The rollout of DSRC goes beyond this very early-stage pursuit of a connected vehicle environment application, however. DSRC is the choice by DOT for all “active safety” operations involving vehicle-to-vehicle and vehicle-to-infrastructure applications.

It is interesting to note that, by virtue of this type of advanced technology, DOT and private enterprise are teaming up to transform the heavily energy-intensive and individual-vehicle-based national highway system into an intelligent system that, over time, could become a true mass transit alternative and part of a new network of connected intermodal systems.

Near-Term Systems

Transit system technology that is already in broad use, or close to widespread adoption, includes solutions and tools that make it possible to operate transit functions such as service scheduling, capacity and speed control and monitoring, system analysis optimization, station location supply and support, fare economics modeling, ridership management, financing, regulatory compliance, selection of performance levels, and selection of transit modes.

The bulk of these functions at one time were conceived, built, and operated in-house, within a straightforward hierarchy of authority and responsibility. In contemporary transit system management, however, the information technology must be designed to, in a secure and organized fashion, facilitate exchanges between stakeholders who maintain great differences in priorities. These include private enterprise contractors, consumer and merchant organizations, metropolitan planning organizations, real estate management companies, funding entities, and regulatory oversight panels at the regional, state, and national levels.

On the hardware side of the transit equation, equipment designers and engineers around the world are moving forward on many fronts with some progressive goals—some mandatory, others voluntary—that are somewhat universally prized.

For instance, the ideal of sustainability, that transit vehicles and infrastructure must be built and operated in ways to minimize energy waste and environmental degradation, is virtually inarguable. This single principle, so widely accepted, already has driven some very practical outcomes in transit system technology decisions.

In the Denver, Colorado, metropolitan area, for example, city and regional authorities took great pains to work with academic researchers, government advisers, and private industry contractors to devise an integrated multimodal transit network to meet the area’s growing mobility needs for decades to come. The process is being managed by the Regional Transportation District (RTD), the main transit planning and operational body for the area.

Throughout this process, environmental sustainability was near the top of all priorities; related constants were the need to abate and mitigate noise pollution and support better air quality.

The resulting system, called FasTracks, embodies that principle of sustainability across all modes: light rail, commuter rail, bus rapid transit, and streetcar transit. Each mode was selected for particular zones and to fill specific transit need niches. Each mode is being installed and built out in accordance with its projected contributions to system-wide metrics.

The managers for each of the modes are purchasing and deploying technologically advanced infrastructure and vehicles designed and modified for specified levels of rider comfort, line capacity, transit speed, and other metrics, within the overall system budget requirements.

The application of goal-directed planning and budget processes to the FasTracks system does not stop at the doorstep of an express bus or on the station platform of a light-rail train, however. With true “system” awareness, FasTracks and RTD incorporate a holistic approach to the transit network.

This means that transit-oriented development (TOD) is applied to areas in the vicinity of system lines and stations. TOD is an approach to transit system development that takes into account the options for neighborhood improvement and economic stimulation that arise during major build-outs of transit systems. Property values, parking, congestion, pedestrian amenities, and many more urban considerations are accounted for in this approach. By applying the TOD principles, the

transit authorities seek to gain such benefits as the following:

- Reducing sprawl and protecting existing neighborhoods
- Reducing commute times and traffic congestion
- Improving environmental quality and open space preservation
- Encouraging pedestrian activity and discouraging automobile dependency

Each of these principles helps transit system developers refine their applied techniques, which in turn lead to more intelligent, sustainable, and value-enhancing decisions regarding technology.

Transit Systems

Mass transit, public transport, and public transportation—all usually synonymous terms—refer to transportation services that are typically provided by a government entity and available to the general public.

Transit is different from services such as taxis that are not available for simultaneous use by multiple members of the public (vanpools present one notable exception). Transit services generally charge a fee for use and operate according to a published timetable.

In most of the world, essential public transport services are provided by units of government as a public or social service. While such services are expensive to operate, and most transit systems operate at a loss and require public subsidies, many scholars and activists argue that safe and reliable mobility options are essential to a functioning society. Other scholars, however, point out there is nothing inherently universal about public transit, and its usefulness to society is fungible rather than essential.

While there have been notable examples of privatized forms of public transportation in recent world history, most fail to sustain themselves financially without significant public investment in infrastructure or outright subsidies by governments.

Because the most fundamental infrastructure resources of public transportation—roads, sidewalks, turnouts, benches, and bus stops—are publicly owned, in addition to the need for subsidies to

remain solvent, the vast majority of transit agencies are publicly owned and operate with a monopoly on a geographical area.

History

While the history and origins of all modes of public transport are not completely known, water taxis, a boat for water crossing available for a fee, are the first known forms of public transportation. Ancient Greeks were said to bury their dead with a coin under their tongues for fare on ferries to take them to Hades.

North American public transport also revolved around water-based forms until the early 1800s. Horse-drawn carriages were introduced in New York City in 1827 and expanded to include a horse-drawn railway in 1832.

Cable cars, as popularized today in San Francisco, California, were the first mechanized public transport vehicles in 1873. While a number of cities—including Chicago, Illinois, and New York, New York,—utilized cable cars, only San Francisco's system remains. Cable cars were soon followed by electrically powered streetcars, first used in Richmond, Virginia, in 1888.

Boston, Massachusetts, and New York City opened subterranean subway systems in 1897 and 1904, respectively, but streetcars operating in public rights of way and sharing their route with other forms of transportation, became ubiquitous in North American cities in the first decades of the 1900s, eventually used in 370 U.S. cities by 1912.

Except for those in Seattle, Washington; Detroit, Michigan; San Francisco; New York; and Boston, practically all transit companies were privately owned, and most were forced into bankruptcy in the 1950s and 1960s as suburbanization became the primary form of development, the population in cities plummeted, and Americans' love affair with the private automobile grew exponentially.

Transit, unable to compete with major public investments in roads and highways, fell from its high of 23.4 billion passengers in 1946 to just 10 billion a decade later. Cities all over the United States scaled back or canceled public transit expansions. By 1970, only seven streetcar systems remained in cities, including San Francisco, New Orleans (Louisiana), Newark (New Jersey), Boston, Cleveland (Ohio), and Philadelphia (Pennsylvania), and public transit ridership had further fallen to 7.3 billion.

Two streetcars running parallel to each other on Canal Street in New Orleans, Louisiana, in May 2013. Unlike light rail systems, streetcars often share a roadway with other traffic.

Responding to the bankruptcy crisis threatening transit systems all over the country, in 1964 Congress passed the Urban Mass Transportation Act, which provided grants and loans for cities and states to purchase these struggling, privately owned transit companies and operate them as public agencies.

The act also created the Urban Mass Transportation Administration (which would become the Federal Transit Administration [FTA] in 1991) to oversee and regulate transit agencies receiving federal funds. President John F. Kennedy and Congress saw public transport as a way to mitigate traffic congestion, worsening air pollution, sprawling land use development patterns, and the physical and social isolation of those unable to operate a private automobile.

Public investment in transit helped stabilize transit ridership, increasing from a century low of 6.5 billion passengers in 1972 to 10.2 billion in 2010.

Transit agencies in the United States employed just under 400,000 individuals in 2010.

Modes

Presently, there are a variety of modes, or types, of public transport vehicles: airplanes, buses (including trolleybuses), water ferries, and rail (streetcars, light rail, heavy rail, and commuter rail). All use some form of infrastructure, whether roads, airports, seaports, tunnels, or fixed guideways (for example, rail tracks or overhead electric cables).

According to the American Public Transportation Association, as of 2010, only one U.S. metropolitan area uses cable cars, 35 utilize light rail, 51 provide ferryboats, and 676 maintain bus systems. Each mode is discussed below.

Buses, first introduced in 1922, began to replace streetcars in many U.S. cities by the middle of the 20th century. Transit providers preferred the rubber-tired vehicles because of their lower start-up costs, but primarily because of the ease with which they could be re-routed to serve new or different neighborhoods.

Public transportation buses can serve locales of any size, provided they have roads. The United States' 66,239 public buses carried 5.2 billion passengers in 2010, over half of all transit riders, but roughly half the 10.7 billion passengers they carried at their peak in 1948. Buses continue to be the "workhorses" of the nation's transit systems, operating at longer distances and for longer hours than any other mode.

At an average speed of 12.9 miles per hour (mph), however, buses are also one of public transport's slowest modes because they generally do not have their own rights-of-way and are dependent on external traffic conditions. In contrast, bus rapid transit (BRT) operates with its own dedicated right-of-way and automated traffic signals giving buses priority, thus maintaining higher speeds. This relatively new form of bus service was first deployed in the United States in Los Angeles in 1973 and is beginning to become more popular in other global cities, including Mexico City, Mexico, and Johannesburg, South Africa.

Buses can be powered either by onboard fuel (most often diesel) or by electricity via overhead electrical lines. These vehicles, known as trolleybuses, are occasionally differentiated in literature on public transportation. Buses occupy a notorious

position in American culture, inextricably linked with poverty and users who have no better mobility options.

There are different types of railway transport: light rail, heavy rail, commuter rail, and streetcars. Distinctions between the types are frequently vague, but railways in general refer to a family of public transport vehicles designed to operate on fixed, guided, steel rails and, with the exception of streetcars, in exclusive rights-of-way. Rail systems, unlike bus systems, must build and maintain their own tracks, stations, and rights-of-way.

Light rail and streetcars, as opposed to heavy and commuter rail, are intended to be constructed relatively quickly, serve more frequent stops, and require a smaller investment in infrastructure because of a lower weight load. Light rail, utilizing its own right-of-way, generally operates at street level (for example, Minneapolis, Minnesota's Hiawatha Line).

Streetcars, also at street level, share the roadway with automobiles and, occasionally, pedestrians (for example, New Orleans' Canal Street streetcar line or Portland, Oregon's Tri-Met's streetcar line on the Portland State University campus).

Both light rail and streetcar vehicles can operate singularly or in tandem with multiple vehicles to accommodate different passenger loads. Light rail in the United States in 2010 carried 457 million passengers, up from 320 million in 2000. Thirty-five U.S. cities use some form of light rail public transport, up from less than 10 in 1970; these services average 15 mph when in service.

Heavy and commuter rail, collectively known as rapid transit, refer to high-capacity, high-speed systems, operating entirely in their own rights-of-way. Heavy rail, more popularly known as a subway, is built underground about 50 percent of the time (for example, the Bay Area Rapid Transit [BART] subway in San Francisco, California, or the London Underground), 20 percent of the time on elevated tracks (for example, the Chicago Transit Authority's CTA's "L" trains), and the remainder at ground level.

Commuter rail (for example, Nashville, Tennessee's Music City Star) frequently shares tracks and infrastructure with freight rail lines—being built at ground level 90 percent of its length—and typically serves widely spaced suburban stations with extensive park-and-ride facilities. Twenty-eight U.S. cities with commuter rail transit—up from less than

10 in 1970—carried 464 million passengers in 2010 at an average of 33 mph, the fastest of all modes of public transport.

Fifteen U.S. metropolitan areas with heavy rail systems—up from 10 in 1970—collectively carried 3.5 billion passengers, roughly equivalent to the number of passengers on Tokyo's subway alone. Heavy rail in the United States operated at 20 mph, on average, the second highest speed among modes.

Ferryboats, used in 51 U.S. metropolitan areas, represent the oldest form of public transport in the United States and world. They are also the largest public transport vehicles and the slowest, at just under 10 mph. However, ferries can greatly shorten distances ordinarily traveled around bodies of water. Ferries are capable of carrying passengers, and some transport automobiles, too, blurring their distinction as public transport.

In 2010, ferry boats in the United States carried 90 million passengers, half of which occurred within just two transit agencies, Washington State Ferries and the New York City Department of Transportation.

Fares

On all but a few public transport systems in selected cities in Europe, and with the exception of discounts provided to certain populations, most public transportation services are provided for a fee that each passenger pays at the time of service, either with cash or a prepaid card.

Fares usually constitute a fraction of the actual cost of the service, and the ratio of the fare to the actual cost is known as the “farebox ratio.” The higher the farebox ratio, the lower the subsidy provided by taxpayers, but users may also be paying a higher fare than on comparable transit agencies. On average, most transit operations receive 55 percent of their funding from direct government assistance, with the remainder obtained through fares, advertising, leasing arrangements, or other sources.

Fares on public transport in the United States totaled \$12.5 billion in 2010. Agencies, while bound by local or state regulations, are able to charge fares as they see fit, and there are distinctions between the ways fares are assessed. Some agencies charge a fixed fare, in which passengers pay the same fare no matter how far they travel. Other agencies charge fares based on length of travel or by assessing geographic zones that differentiate fare costs.

Some social justice advocates claim fixed-fare policies unfairly shift fare burdens from suburban populations, who typically travel longer distances to inner-city populations, typically poorer than their suburban counterparts and who travel shorter distances. Zone-based fare structures, however, can be difficult to administer and collect, and some argue they lead to higher costs for all riders.

Funding Controversies

A number of transportation scholars point out that while 20 percent of all federal transportation funds are spent on public transportation, most states fund it at much lower levels—sometimes offering nothing to public transportation agencies. In spite of the fact that over 20 percent of African American, 15 percent of Hispanic, 13 percent of Asian American, and 7 percent of white households do not own a car, transportation funding at the state level tends to accrue for the benefit of private automobile owners.

Further, when differentiating among public transport agencies around the country, heavy and commuter rail services, more often used by suburban and more affluent patrons, are subsidized at significantly higher rates than bus services, effectively lowering costs for rail users at the expense of bus riders. Commuter rail, the public transport mode of choice for whites, is subsidized at far higher rates than bus systems, which are primarily used by poor Americans of color.

Transit Systems, Marketing Research and Public Relations for

Marketing is strictly the science of determining what consumers are willing to buy and how much they will pay, and, therefore, marketing planning should be an important part of the planning of any transit improvements. Through the marketing planning process, improvements that will be used can be identified, and an assessment can be made of the economics at the price consumers will pay.

The science of potential customer feedback is well established in the domestic consumer industries, where prototypes of new products can be shown to consumers, who are asked for evaluation. Clearly, this is not usually practical for a new transit service. Spending time at an early stage can help transit authorities avoid wasted expenditures on a service that will not be used by enough people to be economical, or that will need expensive retrofitting to overcome problems that could have been identified and designed out before construction began.

Launching a New Service

Once a decision has been reached on implementing a transit improvement, public relations (PR) and advertising come into play. PR is about handling issues, usually complaints, personally addressed to the transit body or its agents.

Many companies use PR as a surrogate form of marketing and studiously reply to every complaint. Follow-up studies have shown that feedback to such complaints is shared positively by the complainant with about 20 friends and family, creating a good image for the organization. No response or negative responses to complaints have the opposite effect.

"The medium is the message" wrote author and academic Marshall McLuhan. Often, low-cost advertising is more effective at raising consumer awareness than expensive media, such as television. The most effective advertising is personal recommendation but getting that is a real challenge when a new service is launched.

Almost everyone needs to travel, and so this can be the starting point for a launch. Most journeys are made by car, so the launch needs to get people to consider the transit option for particular trips. Usually, there will be a "pre-launch teaser" advertising campaign. This can include incentives to encourage people to contact an organization for information or a prize in return for registering their personal contact information, including, where possible, mobile phone numbers. Advertising through cell phones is now an important communications tool.

Adults are also influenced by their children's pestering them. Getting a message to children through public education programs in local schools, for example, can build awareness in families and communities with messages supporting transit. Children are often environmentally aware, so a transit is "green" message can be a powerful way to get families to try the new service when introduced. Developing competitions for children (for example, coloring or essay contents) as part of the launch, together with introductory discounts, can be a first step to getting a new generation to choose public transit.

Teenagers are the most mobile sector of the population, and many resent having to be taxed by parents, which explains the importance of the rite of passage in gaining a driver's license. Teenagers also have disposable income and are often environmentally aware. If the new transit service is marketed to teens as an option for travel "freedom," this could be a big attraction, especially if it includes riding with groups of their friends.

Why People Do Not Use Transit

This can be a killer question, because getting more users and building a wider clientele is key to

ensuring the success of a new transit service. Market research targeting non-transit riders can be illuminating. Responses range from factual (there is no transit service available) to emotional (it is not good enough, or I don't like the people who are riders).

Factual reasons for not riding transit can be addressed. For example, people often think that transit is too expensive, without realizing how expensive it is to own and drive a car, especially when fuel is only bought infrequently with a credit card, so the cost does not register for a particular journey. Most European transit services now sell travel by time, with tickets available for unlimited trips for one hour, one day, one week, one month, or one year. Such tickets can be automatically paid directly from a bank account or from a cell phone. Emotional reasons can be more difficult to address. There are many examples of advertising campaigns, though, that have addressed emotional issues indirectly.

One example occurred in the city of Brussels, Belgium, where transit patronage had been falling for some time. Market research showed that part of the reason was that ticket inspectors with military-style uniforms were seen to be a quasi-gestapo. This led to a long poster campaign displaying the ticket takers in a new "softer" uniform that had been introduced in response to the market research. The posters featured the faces of different inspectors with captions such as "Uncle John here to help you get safely home."

Within six months, public attitude to transit in Brussels improved, and after one year, patronage started to increase, and this has been the case ever since. Growing patronage also provides transit agencies with confidence to invest in new services, which then reinforces the image that transit is progressive.

Addressing Negatives

There are negatives as well as positives to public transit. Transit may not be convenient, it may not serve the places to which many people travel, and it could be perceived as too slow, too expensive, too dirty, unsafe, or unfriendly. Some of these perceptions can be misconceptions, although they may be difficult to overcome.

There are direct and indirect ways in which negative perceptions can be addressed. The direct ways include the usual advertising and promotional methods. The indirect ways include working with

producers to have transit travel and/or locations written into TV series, featured on TV news, or mentioned by opinion leaders in press articles or on social media. The latter can be facilitated by special press events and tours.

PR in a Crowded Media World

Transit is not the only product vying for the attention of the public. Countless commercial products and services, from consumables like food and drink to durables like cars and home appliances, are advertised to consumers with huge budgets on television, radio, the Internet, billboards, newspapers and magazines, and even public bathrooms.

In contrast to consumer goods, transit is a public good that confers benefits to individuals. Although getting that complex message across can be difficult and expensive, it is vital if the transit "product" is to be properly positioned in the consumer marketplace.

Developing the Positives

Transit is green (that is, environmentally beneficial), which is an important characteristic in these environmentally conscious times. Streetcars, subways, light rail, and trams are proven to attract people away from their cars, at least for certain trips, such as commuting.

Most businesses depend on repeat customers. For transit, the daily commuter is an example of a repeat customer. With its spikes of peak usage near the beginning and end of the workday, though, daily commuters place the greatest economic strain on the cost of transit operations, with a large capacity required for only about 20 percent of the weekday. At other times, there is spare capacity, which effectively has an almost no marginal cost of operation.

This pattern provides an opportunity for transit services to attract off-peak trips by lowering fares or creating special deals, such as pairing a transit fare with tickets to entertainment or other leisure activities. Transit also can be a very sociable mode of transport, so clubs, schools, and informal groups can be encouraged to travel off-peak, especially if transit is linked to an activity at the journey's destination.

Case Studies

In 1979, the newly formed transit cooperative company in the Rhine-Ruhr region of Germany changed

its fare system from paying by distance traveled to a flat fare, with an average fare increase of 10 percent. This change was preceded by advertising on billboards and leaflets delivered to homes and distributed at transit stops explaining how the new fare system would work. Based on past experience, a 10 percent increase in fares was expected to result in a 3 percent decline of patronage but a 7 percent increase in overall revenue.

Much to everyone's surprise, patronage grew by 4 percent after the change, resulting in a revenue increase of 14 percent, much larger than the budget. This extra revenue was then reinvested in service improvements, which started a self-funding virtuous cycle of rising transit patronage and revenue.

Why was this counterintuitive experience achieved? Analysis of passenger attitudes showed that the advertising campaign had for the first time presented a positive image of transit, with a new product implying confidence in the service. This was reinforced by the use of colloquial language and avoidance of "officialese."

In 1986, bus services in the United Kingdom were deregulated. From 1933 until that time, all bus services had been tightly controlled, effectively giving operators monopoly rights for large areas in return for running socially necessary but unprofitable services, cross-subsidized by profitable trunk bus routes.

While this was an acceptable solution in 1933, when most people were transit dependent, that was not the case in 1986, when bus services were heavily subsidized by the state. With deregulation, bus companies could run any service at any time in a competitive market on a purely commercial basis. In the run-up to deregulation, a number of new bus companies were formed.

One of these was the BeeLine Buzz Company, which planned to run minibus services at high frequency along a few key routes in Manchester. BeeLine targeted teenagers and, as part of its promotion, had a billboard campaign along the intended routes. T-shirts were also given away at schools and youth clubs with the company name and logo.

The incumbent bus company answered this with a series of expensive TV commercials. Once running, BeeLine soon built up a substantial patronage, which forced the incumbent bus operator to reduce services. Market research follow-up six months after the BeeLine service began showed a

very high recollection of the original bus company's TV advertising campaign—but most respondents thought it was for BeeLine. While the big bus company wasted its money, little BeeLine became the market leader.

In Basel, Switzerland, a "Rainbow" monthly discount ticket was launched with the aim of attracting commuters who would leave their cars at home and use transit instead. Although the ticket was set at an attractive fare, a slight loss was budgeted because the expected increase in ridership would also increase peak capacity. In practice, though, double the number of drivers forecast signed up for the Rainbow ticket, resulting in the operator making a surplus. Meanwhile, because of the reduced road traffic and congestion, the operator was able to increase peak capacity without any extra costs.

The Right Medium as the Message

As the case studies above demonstrate, effectively getting the transit message across does not need to be costly if the right medium is used and the message is credible. To get the message right requires both market research and product improvement, which should involve the feedback of both existing passengers and those who do not ride transit. A strong and growing medium combines personal communications and social media in the form of cell phones connected to services such as Twitter, Facebook, Instagram, Tumblr, and others. Indeed, these media allow the transit operator to tailor the message to both existing and potential riders.

How can transit agencies reach cell phone users? Existing riders can be given an incentive, for example, to pay by cell phone through a downloadable application. Potential riders could be courted through a teaser campaign with a big prize offering, such as an all-expenses-paid vacation. The cost of the prize could be small compared to the awareness and access to market research data that can be obtained.

The Message

A transit operator able to boast that ridership is growing has a strong message for nonriders: "What are you missing?" Messages also can target taxpayers who underwrite transit in many cities. Using social media, agencies can receive rapid feedback on the effectiveness of the message, which can be adjusted to resonate with that feedback.

Selling the Transit Product

While a majority of people need to travel for work, school, shopping, health care and other reasons, most people have considerable choice over their mode of transport and the time of travel. The personal car gives people the ultimate convenience and travel flexibility. This, of course, breaks down when the car becomes a mass mode of travel and the society has neither the funds nor the willingness to devote large parts of urban areas to provide enough road capacity to allow noncongested driving at peak times.

Transit can play a role in keeping cities civilized, but transit must be provided in a form to which car commuters are willing to switch. As many cities have shown, attracting car commuters to transit allows road capacity to be reduced and released for other value-added activities, or even converted into green space. This can be a major benefit to the whole community (for example, by reducing local taxes or providing better services).

Therefore, a partnership between the transit operator and city hall is needed to find the best way to attract car trips, allowing the operator to sell transit services to an increasingly willing population.

An example of how this can be achieved was the referendum required to raise the sales tax in Dallas, Texas, to enable the first Dallas Area Rapid Transit (DART) line to be built in the 1980s. A follow-up study asked people why they had voted to increase their taxes. The message was that "DART would get other car drivers off the road and make my commute quicker."

In many consumer industries, up to 10 percent of revenue is devoted to advertising and promotion. Few transit operators manage 1 percent. Indeed, in the United Kingdom, for every dollar the transit industry spends on advertising and promotion, the automobile and related industries spend \$100. In the absence of such a large budget, transit needs to be smart in its approach, especially by targeting key urban population sectors.

Transit Systems, Service Quality of

Transit systems provide a mobility alternative of fixed and scheduled routes, which jointly induce network effects. The economies of scale, the increasing returns to scale, and the efficient space utilization associated with transit systems make them an efficient and effective means of transport that yields benefits to individual travelers, as well as social benefits to the community.

Furthermore, transit systems can contribute to more sustainable transport overall by reducing car congestion, emissions, and energy consumption and improving traffic safety and social inclusiveness. Thus, the improvement of level of service (LOS) of transit systems is always an important agenda of stakeholders and transport providers.

Regardless whether transit systems are considered a public good or market product, or anything along this spectrum, service quality is an important determinant of a system's attractiveness and, hence, influences the transit market share. Therefore, the underlying administrative and operations environment should support a quality-oriented service development.

Determinants and Indicators

In measuring their accomplishment in providing good services, transport authorities and providers use many standardized indicators based on their

passengers' travel satisfaction, such as comfort, value for money, punctuality, and so forth. Because those passengers have basic requirements that need to be fulfilled, the customers will be extremely dissatisfied if these requirements are not fulfilled.

On the other hand, the customer takes these requirements for granted, and so their fulfillment alone will not increase satisfaction. While fulfilling these requirements will only lead to a state of "not dissatisfied," they are regarded as prerequisites and are in any case a decisive competitive factor.

Based on the extensive literature on transit LOS, the following service aspects have been identified as important determinants of service quality:

- *Accessibility*: Providing a universally accessible service with respect to geographical coverage, social inclusiveness, affordable service, and minimal physical and mental barriers.
- *Availability*: Enabling customers to rely on transit services throughout the day and week, and to enable them to carry out daily activities by providing reasonable service frequency.
- *Ease-of-use*: A user-friendly system allows travelers to acquire relevant and timely information, help them orient themselves in the system, and pay with a simple ticketing scheme and fare collection solutions.
- *Directness*: In order to be competitive, transit service must provide a reasonably direct connection at a good speed when compared with alternative travel modes.
- *Reliability*: The delivered transit service should adhere to the planned service schedule as much as possible. This implies a punctual and regular service that meets the expected duration of the journey with no cancelled or delayed services or overcrowding.
- *Connectivity*: A well-connected network facilitates seamless transfer between lines, as well as other modes of transport. The main determinants of connectivity quality are clear directional guides, information, timetable coordination, facility design, and a common ticketing system and linkage with access and egress modes.
- *Convenience*: Service comfort depends on waiting and onboard conditions, including the following service dimensions: temperature, amenities, service, crowding, and driving smoothness.
- *Appeal*: The perception of service quality also depends on transit stop or station and vehicle design, as well as fleet age, cleanliness, branding, staffing, and fellow travelers.
- *Safety and security*: Service quality depends on a low perceived risk with respect to intentional attacks, crime, technical failures, and health impacts. The sense of safety and security depends on lighting, staff presence, surveillance systems, and the absence of other health-threatening factors.
- *Responsiveness*: The ability of the transit system to adapt itself to changes or unexpected events includes offering replacement service and addressing customer care inquiries.

The manifestation of the quality aspects mentioned above depends on the integration of transit systems in urban and regional development planning, as well as on information and communication technologies (ICT) advancements. The interface between transit systems and the geographical distribution of activities is fundamental to service quality.

The implementation of advanced public transport systems (APTS) facilitates new mobility solutions and services. In particular, the availability of real-time information, Internet connection, and other ICT enhancements can reduce the perceived waiting and in-vehicle times.

The minimal quality requirements of transport services are usually set in the contractual relationship between the public transport authority and the transport operator. The requirements describing the acceptable quality level usually derive from the national transport policy. Thus, transit authorities are delegated by the respective political bodies to guarantee a minimum level of transport service quality is met. These requirements include the following:

- Accessibility, the maximum walking distance from each facility to public transport service

Connectivity is an important aspect of determining the quality of service offered by a public transit system. Passengers want to be able to transfer between lines seamlessly, which makes clear directional guides, timetable coordination, and updated connectivity information extremely important.

- Availability, in terms of public transport trips per hour (frequency) and the service span (length of operation within a 24-hour period) as a function of the development area size and its location
- Crowding level, the level of standing capacity utilization on the busiest trip
- Reliability, expressed either in terms of punctuality—deviation from planned timetable—and/or regularity, which is the deviation from planned headway between consecutive vehicle arrivals

Measuring the Quality Indicators

The rapid increase in deployment of geographic information systems (GIS) and automatic data collection methods (ADC) in the transit sector enables

the generation of various quantitative quality indicators based on extensive empirical data. In some cases, quality indicators might even be available in real time and support supply-and-demand management strategies.

Benchmarking is increasingly used as a tool to analyze and compare various quality measures across stakeholders in the transit industry. The comparison facilitates the identification of problem areas, priority areas for improvement, and ways of sharing information regarding best practices. It is common practice to carry out satisfaction surveys on a regular basis in order to monitor and evaluate perceived service quality. The results of such surveys are often embedded in the contractual incentive agreement.

The values of these quality factors among public transport users (and potential users) can be measured using stated-preference surveys (where respondents state how much they value a particular feature) and revealed-preference studies (based on observation of the choices people actually make when facing trade-offs between various attributes). In conventional planning practices, qualitative factors, such as travel convenience, comforts, and security, were translated into monetary values.

It should be stressed that the subjective nature of perceived service quality implies that it is subject to contextual and cognitive biases. Measurements of service quality based on reported satisfaction levels are therefore dependent on travelers' expectations, social norms, and retrieved situational awareness.

Why does this matter? Experienced utility directly reflects satisfaction with the service level of transport. In transport planning aiming to improve the service level, it is therefore advisable to measure experienced utility instead of, or as a complement to, decision utility inferred from choices. Without this knowledge, there will be no reliable answer as to which of the two notions of utility really matters in making real impacts for customers and potential customers.

Transit Systems Analysis

Transit systems analysis is a discipline employing various methods and technologies to acquire, compile, measure, monitor, and analyze data related to the performance of passenger transportation modes and networks. Typically, it is a function focused on public transit operators and is carried out either by those operators, by outside auditors, or by government agencies specifically tasked with researching and implementing improvements and modifications to public transit.

Beyond the actual physical inventory and physical performance metrics of the transit system's installed base, systems analysis usually also examines the human resources profile, decision-making flow, telecommunications and technology support infrastructure, fare- and fee-collecting performance, budgetary priorities, debt and financial status, fiscal compliance, and reporting requirements.

Broad Mandates

Public transit systems analysis provides transit systems authorities with a means to continually gather and utilize data needed to monitor management performance and guide decision making. It also provides the information output needed to adequately report to government oversight agencies, funding sources, insurers and legal claims boards, tax panels, and similar bodies.

Systems analysis for transit operators is vital in order to contrast and compare the performance and quality of a particular transit network with those of

networks in other jurisdictions. It is also vital for the twin needs of providing lawmakers with clear and verifiable feedback on transportation initiatives, and providing procurement management and staff with time-sensitive parts, equipment, personnel, and expertise needs so that appropriate contracts, invoices, and payment schedules can be supported.

All of these forms of utilization of various data streams are in essence mandates that must be fulfilled by the transit systems' analysis team and its tools. Without accurate and timely data, not only is the ongoing smooth operation of a transit network in jeopardy, but the future status of the network can be placed in doubt when the planning process is set back by missing, inaccurate, or misleading information.

Implemented, upcoming, or potentially available state and federal grant programs are one example of the type of critical financial support that cannot be obtained or sustained without provision of required data. The ability to research, attract, apply for, secure, deploy, and administer such critical funding resources is a core competency in any major urban transit agency or state or regional department of transportation.

Systems analysis helps support these efforts, directly affecting the agency's capacity to purchase rolling stock; improve byways; gain needed services for elderly, disabled, and indigent citizens; and other necessities. The data sets can also help make the case for the fiduciary or consulting assistance needed to assess the network's long-term soundness, to improve its accessibility, to develop partnerships with other public authorities for such projects as intermodal and regional transit links, and to forge mutually beneficial relationships with private entities.

Operational Oversight

In the ongoing, day-to-day operations of a transit system, managers need to dependably "look over the shoulder" of dispatchers, drivers, engineers, mechanics, conductors, ticket agents, safety and security officers, and other employee and associate categories of workers. The productivity of each individual, group, category, location, and department must be monitored, maintained, reviewed, and, if possible, improved.

The on-the-job decisions and actions taken by any one category of transit workers is likely to affect the conditions and situations faced by all

other workers. For example, the dispatchers' decision making on rescheduling to adhere to hourly carrying capacity goals and requirements on a particular line will be made based on information they obtain via electronic monitoring of traffic volume and vehicle spacing, voice communication from drivers and engineers, and any alerts from safety and security teams.

In the aftermath of the dispatchers' decisions, the status information is then updated and may affect each of those worker positions on alternate lines of the network. There are few if any decisions made that have only isolated outcomes.

Robust transit systems analysis tools need to help dispatchers and others in the network to predict outcomes to altered scheduling, but such tools must also be streamlined sufficiently to simplify and shorten the dispatchers' choice-selection option list in a reasonable available time frame. When provided with data from such streamlined systems analysis, dispatchers can improve the effectiveness of their decision-making activity and thus help solve and reduce real and potential delays.

Such outcomes will tend to help maintain operational effectiveness in a range of other functions, such as employee safety, customer safety and ride assurance, rolling stock maintenance, overtime reduction, and exposure to internal or external insurance and legal claims.

In many cases, the trial period of a proposed new operational rule set requires that the transit system operator rapidly gain an understanding of the long-term usefulness of the rule set under actual conditions and diverse scenarios. By applying arrays of street, station, and intersection sensors and wireless telecommunications of data with database sorting and display tools appropriate to the trial, the operator could, for instance, more quickly and reliably gain confidence in results.

Developers of transit systems analysis software and interface hardware are aware of these advantages and are constantly seeking to provide improved internal code and external interface modes. A sensor-and-software system to determine shortest-route connections in a transit network is not a new idea, but the technology to deliver such a system is constantly evolving; each new version may present a transit operator the opportunity to pass its established cost-benefit threshold for installing such a system.

Reporting Requirements

In large public transportation bodies, there are many touchpoints with external constituencies and various government entities. Transit systems analysis can help keep communications with this plethora of partners up to date and effective.

The abilities of workers and manager to perform these communications duties are often challenged by (1) the amount and complexity of data needed to assemble accurate and comprehensive reports and (2) the number of corresponding agencies and the degree of variance in their information requirements.

For example, a single unit in the California Department of Transportation—the Office of Administration and Budgets of the Division of Mass Transportation (MassTrans)—is tasked with constant liaison with this range of state agencies:

- California Department of Finance
- California Department of General Services
- California State Personnel Board
- California Department of Personnel Administration
- California Division of Business, Facilities and Security
- California Division of Human Resources
- California Division of Labor Relations
- California Division of Procurement and Contracts

MassTrans is also tasked with liaison with Departments of Transportation in other states, and also with these and other federal and nongovernmental correspondents:

- U.S. Department of Transportation
- Federal Transit Administration
- Federal Highway Administration
- American Public Transit Association
- California Transit Association
- California Association for Coordinated Transportation
- Community Transportation Association of America
- National Rural Transit Assistance Program
- Multi-State Technical Assistance Program
- Local Technical Assistance Program

In its communications with these agencies, MassTrans must conduct information sharing on a range of priority areas, including intelligent transportation systems (ITS) requirements, planning grants, toll credits, and transportation development credits. Additionally, these communications must be made in such a manner as to accommodate at least two separate major constituent domains—the state and the federal—and the language must be tuned to the diverse programs administered within each domain.

Each of these correspondents, along with numerous others, can be an originator or channel of funding or technical support to MassTrans. Therefore, it is imperative that they each be provided with adequate and accurate data derived from performance metrics as acquired and measured by the transit systems analysis tools MassTrans has in place in its various operational modes and networks. As stated in its mission statement, the Transit Systems Analysis Branch (TSA) of MassTrans must generate data

related to the fiscal status and performance of public transit operators throughout California. The TSA Branch is responsible for the creation of a central data source which will provide management and staff the information necessary to respond to inquiries quickly and efficiently.

Transit Tunnels, Design and Construction of

Transit tunnels are enclosed underground passageways constructed for use by transit systems and in many cases—as with subway systems—comprise either the bulk of the network or at least the central portions of it.

The design of a transit tunnel begins with a clear statement about what is needed—the points the tunnel needs to connect, and how many possible routes it may take—before the engineer is free to select the best choice from among multiple possibilities. Based on this defined goal, a geotechnical investigation of the site or potential sites begins.

Geotechnical investigation is undertaken by geologists and geotechnical engineers and reveals information about the soil and rock at a given site so that the correct and safe construction choices can be made. The process involves both surface and subsurface investigations. Surface investigations usually include geologic mapping, which produces a map showing geological information such as faults, folds, foliations, lineations, and exposed geologic strata.

Numerous high-resolution photographs are taken both for documentation purposes and for photogrammetry (the examination of photographs in order to learn about geological features); they can be shared with engineers who are not present at the site, which makes it easy to gather input from them. Thermal scans, high-resolution ultrasonic scans, and radar may be used for further investigation of the site.

Soil samples are taken using small-diameter borings, which allow for an examination of the

stratigraphy of the site. The standard preparation test can be performed on-site and provides information about local soil properties and grain size. Other tests pertain to the seismic conditions of the site, groundwater and groundwater pressure, and subsurface gas concentrations.

The flat plate dilatometer test measures the strain of the soil in response to varying levels of applied stress at different depths, which helps predict the effects of building the tunnel. Later, tests are performed in the laboratory to test the consistency of soil, soil content, the shear of the soil, water content, and other factors, as well as to confirm the results of on-site tests. Geophysical exploration during the investigation can help predict the response of the site to seismic events. This is relevant even in areas that are not known to be earthquake prone, not only because much of the country has the potential to experience an occasional earthquake, even if not

frequently, but also because seismic events that are not severe enough to cause significant disturbance aboveground can still have subsurface ramifications that are especially important to underground construction.

One of the main goals of the geotechnical investigation is to determine the stand-up time (the time the tunnel can support itself without other structural support) of the proposed tunnel, which bears on the plans and timetable for the excavation work. Stand-up time is affected not only by the soil conditions but also by the tunnel shape: the greater the ratio of height to width, the longer the stand-up time, all other things being equal.

Geotechnical investigations also devote a lot of time to studying the groundwater, which is key for tunnel construction to prevent erosion, freezing, and flooding. Hydrologists are usually consulted on groundwater matters. In some cases,

A view from the mezzanine at the University Street transit tunnel station, or Metro Bus Tunnel, in Seattle, Washington. The tunnel runs the length of downtown Seattle for 1.3 miles (2.1 km). Construction began on the tunnel in 1987 and was completed in 1990 at a total cost of \$455 million. In 2005, the tunnel was closed for a two-year project to modify the structure to accommodate light rail.

a site might be found unsuitable for tunnel construction, although usually this discovery is made early in the planning process during preliminary investigations.

Infiltration of groundwater into tunnel elements is the primary contributor to tunnel deterioration, both for older concrete tunnels and for modern tunnels. Groundwater also plays a role in the severity of deterioration induced by freeze–thaw cycles over time. Depending on where the tunnel is being dug, other man-made infrastructure may require relocation, such as electrical cables, pneumatic tubes, and water and sewer pipes. Foundations of buildings or abandoned older construction may also be in the way. In Europe, a frequent obstacle in the construction of subway tunnels is the subterranean ruins of older cities.

Once the tunnel site has been chosen, there are different methods of tunnel construction that are suitable to different conditions. The two principal methods of tunneling for subway systems are cut-and-cover and deep-bore. Cut and cover is the older method of subway tunnel construction and consists of essentially digging a trench and covering it; the surface is removed and the subsurface is excavated, after which the surface layer is put back in place. Subway tunnels dug in this way generally followed the street layout and created subway stations fairly near to the surface.

Cities with older subway systems, originally, at least, had tunnels created with the cut-and-cover method (although not by the machines that would be used for the work today). The method continues to be used because it remains the cheapest, but it often inspires community complaints because of the effect on traffic and the noise in the neighborhood during the construction process.

When Vancouver, British Columbia, used the cut-and-cover method to build its Canada Line in the 2000s, dozens of lawsuits were filed due to the disruption to local businesses. While the largest initially successful lawsuit was overturned on appeal, it still sent a warning signal to other metropolitan areas considering cut-and-cover.

The more recent deep-bore method begins with a hole dug somewhere along the proposed tunnel route into which a boring machine is inserted. Once running, a boring machine excavates a circular tunnel at a rate of up to 80 feet per day. Tunnel borers are transported piece by piece to the site,

due to their size and weight, and consist of scrapers and discs that crush rock and debris in front of the machine. A conveyor transports the crushed remains to the machine's wake, where a tunneling crew collects and disposes of them.

Unlike cut-and-cover tunneling, deep-bore tunneling does not interfere with surface activity, except at the point where the boring machine enters. Streets and other structures function safely and normally while the boring machine is excavating below. Deep-bore tunnels are located farther beneath the surface than cut-and-cover tunnels and are much more expensive. However, much of that cost is the initial capital investment, and that can be somewhat absorbed if an extensive tunnel system is planned.

This is especially the case if the goal is to create a basic system at first and then continue to expand it over time, keeping the expensive boring machine in use and thus continuing to extract value from it. Deep-bore construction is not possible in all areas. The groundwater does not always permit tunnel construction far below the surface, or soil conditions may not be amenable. Deep-bore construction also requires deeper stations and, in practice, deep-bore routes are usually assigned fewer stations, which dictates a different sort of route map.

Transit tunnels are generally touted as benefiting local business, but the increased traffic that brings those economic benefits can also bring significant noise and air pollution. Tunnel construction is often an area of concern, as its effects may be felt farther from the site than originally projected, and it may be disruptive to local construction (including historic buildings), local businesses, residents, and ecosystems. Disasters also cast a negative pall on such tunnels, and past problems may be brought up when new plans are considered. For instance, in 1995 the collapse of a portion of tunnel in the Los Angeles subway led to a sinkhole that consumed an 80-foot-wide area of Hollywood Boulevard. Flaws were later found in the tunnel's design.

One of the most famous transit tunnels is the Channel Tunnel or "Chunnel," which runs beneath the English Channel, the body of water separating England from the European mainland. At 31.4 miles of undersea rail—the longest undersea rail in the world—it connects Folkestone, Kent, in the United Kingdom, with Coquelles, Pas de Calais, in France.

The Chunnel transports passenger trains (the Eurostar service), freight trains, and the Eurotunnel Shuttle. The Eurotunnel Shuttle is a roll-on/roll-off vehicle transport, providing a service analogous to that of a ferry. This allows private citizens to travel back and forth between England and France in their own vehicles, which is a considerable boon to tourism for both regions, making trips easier and more affordable and encouraging casual and impromptu recreational trips.

Projects like the Chunnel had been discussed for decades but always stalled until 1986, when the Eurotunnel company was founded for the purpose of building the tunnel. Construction began two years later, and the Chunnel opened in 1994. The forecast levels of freight and passenger traffic both proved to be overestimations. Passenger traffic (including both the Eurotunnel shuttles and Eurostar's passenger service) peaked at 18.4 million people in 1998, and neared that peak in 2012, with 18.2 million.

Although the 1998 figure consisted mostly of Eurotunnel shuttle passengers (about 12 million), Eurotunnel usage has declined and Eurostar usage has gradually risen. On the other hand, Eurotunnel shuttle usage has increased significantly for freight trucks, while freight train tonnage has decreased steadily since 1998. The Chunnel has also attracted attention because of the attempts of immigrants and refugees to use the tunnel (stowing away on freight trains in most cases) to enter the United Kingdom.

Transit Vehicle Capacities, Loading Criteria and

Although transit vehicles include a wide variety of modes and can range from ferryboats to rickshaws and from taxicabs to pedicabs, the science—and math—of determining the capacity of public transit vehicles and loading criteria most often involves shared passenger transportation services in urban centers. This most often includes buses, subways, and trains and rapid transit systems, under the supervision of a centralized transit authority responsible for ensuring both efficient and safe service. The data is staggering—each year in the United States alone, more than 10 billion passengers avail themselves of public transit systems. On any given day, 35 million people board public transportation; the usage of public transportation in the last decade has spiked more than 35 percent. The volume of traffic using public transit has compelled the determination of capacity and loading criteria to become a science.

The factors that go into determining the capacity of these transit vehicles must take into account not merely seat numbers, aisle width, and seat width but also the capacity of the conveyance to permit standing passengers; then it must factor in what constitutes not only a safe range of capacity but also a bearable ride. Because public transit systems are public services and rely on the business of their passengers (after all, tickets provide the largest share of revenue), capacity determinations must be guided by the pragmatic matters of providing a safe and a comfortable ride for both seated and standing passengers.

In addition, metropolitan transit systems interested in expanding or cutting back on services and lines of transport use transit vehicle capacity determinations as part of the equation in any assessment of current services. Transit vehicle capacity and loading criteria are often critical factors in determining when—and if—public transit services need to be expanded or cut back.

What, urban planners and metropolitan transportation boards ask, constitutes a crowded bus or a packed subway? When the transit vehicle is at peak operation, the critical determinant in vehicle capacity calculations, what volume of passengers

qualifies as a crowd? The math is both precise and intricate.

The International Association of Public Transport has defined load factor as how crowded a bus or subway train has to be in order to justify additional services. In the formula for measuring capacity, load factor is most often represented as the number 1 expanded to two decimal points to represent the percentage of filled seats. For example, when a bus is full, the load factor is said to be 1.00, and there are no empty seats. If the load factor is moved to, say, 1.25, this means that not only is the bus full but 25 percent of its capacity is standing. If the load factor is moved to 1.50, this means that not only is the bus full but in addition, 50 percent of its capacity is standing.

Comfort becomes a problem. How many passengers can fit into a public transportation vehicle? The average tolerable load factor for most city buses, for instance, is 1.25. More than that and comfort and safety are compromised.

Bus Capacity Calculations

The math for bus capacity is impacted significantly by whether the bus is an old-school high-floor bus or a relatively recent low-floor bus. Although both are relatively the same dimension, about 45 feet long and 9 feet wide, the internal design is significantly different and creates far different capacities. In the high-floor bus, passengers must step up to gain entrance to the seat aisle, most often four steps from the street to the floor of the bus, past the driver and the fare meter.

The elevated high-floor design traditionally provided passengers with an impressive perch for viewing the passing scenery; these buses could seat somewhere between 60 and 70 passengers: 45 seated, and the rest standees. But the four steps proved an obstacle for passengers, not only those with physical impairments (indeed, the buses were eventually retrofitted with wheelchair lifts, but they take significant time to engage). The design further tended to clot people in the doorway as passengers negotiated the steep steps in all sorts of weather while trying to pay the fare for the ride and thus slowing down transit service.

In newer bus models, low floors were introduced, allowing passengers to simply step from the street onto the bus. These floors were introduced in the 1990s to make bus riding more accessible for older passengers and special-needs riders. Seating

capacity was in turn impacted—there are fewer seats, on average 38, which makes a low-floor bus capacity closer to 55. However, loading and unloading is made more efficient, as has the use of pre-paid computerized bus fares and PayPal accounts. Because of the low floor and because in high-floor buses standing passengers can line the aisle all the way back, a low-floor bus, although it holds fewer passengers, can actually feel far more crowded, thus impacting determinations of passenger capacity.

In express buses, the load capacity is further impacted by the speed of the buses—in such few-stop routes, the load factor has to be maintained at 1.0, that is, all seats taken but no one standing, as the speeds and stops might be a problem.

High-Capacity Transit

By contrast, high-capacity transit trains move significantly more people at a significantly faster pace than buses. However, train systems operate under similar constraints when determining the vehicle capacity for either a subway car or a high-speed transit line train. Because train car dimensions can vary, vehicle capacity can vary.

In New York City, for instance, the average subway train is 8 to 11 cars long (each roughly 75 feet long, although some are far shorter—closer to 50 feet—depending on the line of service). Thus, it is difficult to determine what the vehicle capacity is for a subway train. The number for vehicle capacity can range from 110 to 175 passengers.

The city's transit authority has measured what it deems an acceptable personal space for strap-holders, that is, the circumference space the average-sized standee (and weight and height variables are factored into the capacity numbers) should expect for both comfort and security at peak riding hours.

Although a generation ago the number was put at 4 square feet around each standee, the number has been significantly crunched to 3 square feet to maintain an efficient and economic subway system. Generally, then, an average subway train of 10 cars with an average loading capacity of 100 passengers per train vehicle can transport 1,000 passengers per hour at peak time.

Over the last 10 years, however, vehicle capacities in subway trains in major cities, particularly in Europe, have been significantly enhanced by the introduction of articulated cars (i.e., subway cars without the traditional cumbersome apparatus of

hydraulic doors between individual cars). Rather, the lines of cars are linked by accordion-like bridges that create an unbroken interior space.

The longer subway car design not only provided a safer ride, as passengers were less likely to be sequestered and apart and hence vulnerable to criminal elements, but significantly improved loading and unloading times. Articulated cars further eased the claustrophobic sense of isolation inherent in the older designs as passengers were freer to move about the entire train. Vehicle capacity increased by as much as 10 percent with the additional interior space. Any model for public transportation systems now recognizes both the physical limitations of public transit vehicles as well as the human factor, that is, the space required by the passengers themselves to provide both a safe and comfortable conveyance.

Transit-Oriented Development

Transit-oriented development (TOD) refers to pedestrian-friendly, high-density areas in close proximity to a public transportation system. Following the principles of smart growth, TOD zones have planned residential and commercial mixed-use development situated within walking distance from a fixed-route public transit station. TOD

projects are expected to foster economic development by boosting property values and mitigate the negative environmental impacts of transportation by reducing automobile usage by local residents.

Developers and urban planners work to create a comprehensive and integrated land use plan that encourages smart growth and new urbanism design principles for TOD projects. These principles include easy transit access, pedestrian friendly site design, residential and commercial mixed-use development, and variety of housing options and housing costs. The first goal of TOD is easy transportation access, allowing residents to live close to public transportation options. These residents can commute to work by walking or biking from their home to a transit station.

The most successful TOD designs concentrate development within two zones of the transit station: an initial quarter-mile zone and a secondary half-mile radius around a transit station. Planners consider the quarter-mile and half-mile zones around TOD development to be the distance an average commuter would walk to and from a transit station. Extending a TOD zone requires increased connectivity, such as regular and frequent bus services radiating from the transit station to facilitate a more interconnected transport system.

The second goal of TOD is spurring economic growth, as development projects reshape the topography of urban property values and embed spatial arrangements that establish new clusters of economic growth. The design of transportation infrastructure is thought to create areas of economic growth that can work with local efforts to create a more competitive regional economy. Long-term investment in alternative transportation infrastructure is an attempt to establish pockets of concentrated economic growth.

Embedded in these economic development initiatives are assumptions about the need to establish a "creative city" through amenity growth, resulting in a TOD designed to attract an expanded ridership of young, creative professionals. According to the creative cities thesis, transit systems meet many of the perceived prerequisites for creative growth by establishing transportation amenities and TOD zones around rail stations to attract capital investment and foster economic development.

The third goal is to reduce the environmental impacts associated with automobile transportation

and mitigate the need to expand infrastructure to meet the needs of urban sprawl. By reducing the number of automobiles on the road during commuting hours, cities can reduce their greenhouse gas emissions. This becomes very important for urban areas that are designated nonattainment zones, which indicates the area has exceeded the Environmental Protection Agency's (EPA) threshold for air pollution. Encouraging public transit use and pedestrian commuting also reduces the need for expanding road capacity. By reducing the need to add more paved highway lanes, there are fewer impervious surfaces that generate polluted storm-water runoff and impact overall water quality.

TOD has become a key feature for rail transit projects. Rail transit, much like TOD projects, is conceptualized as a tool for managing urban sprawl, stimulating economic growth, and reducing environmental impacts, because transit systems establish dense urban corridors for future development projects. The subsequent TOD provides opportunities for cities to reshape their urban form and stimulate capital investment. By establishing dense mixed-use TOD projects adjacent to light rail, commuter rail, and metro stations, planners hope to foster the establishment of livable, economically prosperous, and environmentally sustainable communities.

Light rail and commuter rail stations are designated as either feeder stations or destination stations, which result in different manifestations of TOD projects. Feeder station areas are more residential suburban areas that often have TOD projects that include neighborhood restaurants, dry cleaners, and grocery stores. These feeder stations are usually less dense and have park-and-ride lots.

Destination stations are usually located at the central business district, government centers, or near entertainment venues. These areas have high-density TOD designs that can include mixed-use housing, office complexes, stadiums/arenas, and other entertainment centers. Often TOD projects around destination stations do not have park-and-ride lots and are in areas with few parking spaces. In an effort to reduce automobile congestion and create more space for commercial and residential development projects, many cities modify zoning codes to reduce the required number of parking spaces in areas adjacent to TOD projects.

To make transit-oriented districts around urban rail transit successful, these areas must have

adequate bus connectivity and a pedestrian-bike-friendly infrastructure. Bus connectivity allows for residents to reach feeder-station development zones and allows riders to disperse from destination stations downtown.

To facilitate this expansion, frequent circulator buses must connect with the rail station and quickly move passengers beyond the quarter-mile inner circle and the half-mile outer circle of TOD walkability. To accommodate bike and pedestrian traffic, TOD zones should widen sidewalks, establish bike lanes, and provide safe, well-lit spaces for night travel. Some development areas have bike-share or bike-rental programs that allow commuters to have bike access once they get to their destination.

Some critiques of TOD point to the potential of increased property values to displace low-income residents in the area. These potentially negative impacts of so-called "transit-oriented gentrification" can be addressed by ensuring enough affordable housing options in the TOD zone. Like other smart growth and new urbanism projects, TOD projects should work to ensure a healthy mix of income levels and socioeconomic diversity.

Having affordable housing within a TOD zone can be a way to reduce the number of residents who will be displaced by rising property values. It also serves to make TOD more effective by allowing service-sector employees in TOD neighborhoods to afford to live in the neighborhood. That allows residents to live in the area where they work and encourages the pedestrian and transit usage that makes TOD zones more successful.

Transitways

As metropolitan areas throughout the nation grapple with mounting concerns over traffic congestion, poor air quality, and fossil-fuel dependence, policy makers often turn to public transportation for solutions. Particularly within the context of fiscal limitations, the "transitway" concept is seen as an attractive and cost-effective strategy for improving transit efficiency and alleviating congestion in major travel corridors.

In general, a transitway is an exclusive, limited-access roadway or a travel lane or lanes of a roadway—also called a dedicated right-of-way (ROW)—reserved for public transit. The transitway includes associated infrastructure, such as stations, transit terminals, and park-and-ride lots. Transitways may also be referred to as busways, bus/carpool lanes, high-occupancy-vehicle (HOV) lanes, or commuter lanes, or transit lanes, T2 lanes, or T3 lanes in Australia. Transitways are most frequently associated with buses and trolleys.

Bus rapid transit (BRT) systems often use transitways for the long-haul portion of travel. In some situations, emergency vehicles, taxis, and high occupancy vehicles such as carpools and vans may be authorized to use transitway facilities.

Transitways are a special category of roadway designed to provide faster operating speeds, better trip-time reliability, and an overall higher level of transit service than what is typically provided on arterial streets. When properly implemented, transitways have the potential to maximize the person-moving versus the vehicle-moving capacity of the roadway. This article defines transitways, describes their overall characteristics, and provides an overview of benefits and drawbacks.

The term *transitway* appears to have originated in the Ottawa region of Ontario, Canada, where Ottawa-Carleton Regional Transit Commission (OC Transpo) launched its "Transitway" in 1983. One of the most extensive and successful transitway implementations in North America, OC Transpo's Transitway serves as the backbone of the rapid transit system for the Canadian capital area.

Transitway facilities have been implemented in locations throughout North America, including Pittsburgh, Pennsylvania; Washington, D.C.; the Lincoln Tunnel between New Jersey and New York City; Los Angeles and San Francisco, California; Boston, Massachusetts; Miami, Florida; Houston, Texas; Seattle, Washington; Cleveland, Ohio; and Eugene, Oregon. Transitways can also be found in Bogotá, Colombia, and in Brisbane and Adelaide, Australia.

Transitways in the United States are typically implemented by a state department of transportation (DOT), and can assume a variety of configurations and operating arrangements, from simple provisional lanes to fully grade-separated facilities. Physically segregated transitways include at-grade or grade-separated roadways or lanes developed within a separate ROW, barrier- or buffer-separated roadways developed within the freeway ROW, exclusive facilities developed in the median of an urban street, and arterial bus streets and bus tunnels.

In some situations, freeway, arterial, or shoulder lanes that are not physically separated from other traffic lanes function as transitways. These lanes may be concurrent flow lanes, which are lanes in the peak direction of traffic flow, or contra-flow lanes, which are lanes taken from the nonpeak direction to provide additional lanes for the peak-flow direction.

Transitways may provide further time savings by means of additional transit priority measures, such as bus signal priority and queue jumps. Signal priority for traffic lights uses specialized signal phasing to provide extra time for buses to move through intersections. Queue jumps allow buses to bypass traffic backups at ramp meters, toll plazas, and intersections. Different types of transitway facilities vary in the travel time savings they provide and therefore have different levels of effectiveness.

Benefits

By allowing travelers to avoid congestion on high-demand urban corridors, transitways can offer significant travel time savings compared to adjacent

freeway lanes. In addition to providing faster average operating speeds for vehicles, transitways generally enable higher frequency service, resulting in reduced out-of-vehicle waiting times, and increased corridor carrying capacity relative to regular local bus service. Also, while traffic congestion, accidents, breakdowns, and weather contribute to greater travel time variability on freeways, transitway users experience more predictable travel times.

These benefits provide an improved overall passenger experience in comparison with conventional bus service and may produce increased transit and carpool/vanpool use. This in turn may ultimately lead to increased person volumes without the corresponding increases in vehicle trips and vehicle-miles traveled (VMT) that usually occur with the addition of traditional highway capacity. During the peak hours, for instance, a transitway lane can carry up to three times more people than an adjacent freeway lane. In short, well-designed and appropriately situated transitways can save energy, decrease emissions, and reduce the need for new highway construction.

Transitways can also offer savings in overall system costs and implementation time. Costs vary greatly by type of facility, from \$1 million to \$30 million per lane-mile. Cost comparisons naturally reflect local conditions such as traffic patterns; terrain; the need to obtain right of way; the degree of segregation, if any, from general-purpose lanes; necessary pavement treatments; and the design and operational features of various transit alternatives (for example, standard buses versus high-capacity articulated vehicles). Nonetheless, transitways have been found in most cases to require less capital investment than other capacity improvements, such as highway or rail development.

Factors that have been shown to significantly affect expenditures for transitway facilities include the costs of ROW acquisition or land, overhead walkways for passenger safety at stations, additional passing lanes at stations to accommodate large numbers of buses, and modifications to bridges, overpasses, ramps, and interchanges. Fully grade-separated transitways have the highest capital costs of all transitway types, but also provide the highest travel time savings, reliability, level of safety, and peak passenger capacity.

Another advantage of transitways is their inherent flexibility in meeting the needs of unique local

contexts, including travel demand patterns, safety concerns, enforcement requirements, and available resources. For example, buses can adapt if a roadway is closed or destinations change, and several bus routes can converge on one transitway. This provides the flexibility to tailor service to demand without increasing the need for passenger transfers, which have been shown to be a major factor in discouraging transit ridership. An additional benefit is that transitway implementation may proceed incrementally, with small, independent segments or technologies that become operational as funding becomes available and construction is completed.

Challenges

Many transitways include permanent stations, which provide opportunity for development intensification and diversification along the corridor and around stations. However, transitway stations are typically large and can be difficult to integrate into pedestrian-friendly areas. Because easy pedestrian access to stations has an impact on land development and overall transitway success, the importance of pedestrian-oriented station design is paramount.

Another important consideration is that specialized stations require increased capital outlays, and appropriate ROW may be difficult or expensive to obtain. As an example, multiple lanes may be necessary to allow passing at stations where boarding volumes are high or local and express services are operated concurrently. Studies have shown that transitways, particularly those without grade separation, must be strictly enforced in order to be effective. Without enforcement, interference by unauthorized vehicles such as automobiles, taxis, and trucks can significantly diminish transitway performance and safety, especially when general-purpose vehicles must occupy bus-only lanes to make right turns.

Due to the significant amount of traffic control officers required for enforcement, alternative approaches such as left-side bus lanes combined with boarding islands have been used to increase the effectiveness of transitways. Contra-flow lanes have sometimes been introduced as another strategy to prevent vehicles from entering transitway lanes. The drawback to this option is that it creates a safety hazard for pedestrians who may not anticipate a vehicle coming from the opposite direction.

To keep general-purpose traffic out of the transitway and encourage pedestrian safety, appropriate demarcation such as pavement coloring and roadside/pavement signs should be used, especially at merge points and intersection crossings. In addition, the complexity of transitway operations and the ROW limitations that accompany many applications underscore the need to consider traffic operations management strategies, including surveillance, communications, and control capabilities, early in the planning and design phases.

Other Issues

Other relevant issues that must be considered when implementing a transitway include the compatibility of large numbers of line-haul buses on neighborhood streets; the treatment of disruptions in central business district segments (such as the elimination of parallel parking and restrictions on turning movements by general-purpose traffic) for integration of the transitway with the urban setting; and the affect of environmental factors, such as noise and air pollution, on the activities of the central area.

Transitways are most effective when implemented as regional networks with a system of supporting facilities and services. For example, grade-separated systems such as Ottawa's Transitway, Miami's South Busway, Pittsburgh's transitways, and Bogotá's Transmilenio are operated with integrated networks, including routes that serve all stops and a variety of feeders and express services with integrated off-line and line-haul operation. There are also indications that long-term impacts of transitways may be greater than short-term impacts, reflecting the synergistic effects of various program elements and the influence of marketing and promotional campaigns.

Transportation, Economics of

Transportation economics is a broad field. It is an established branch of neoclassical economics, while also having connections to the theories of the provision of public goods, land use planning, and public-sector financing. Transportation is the means for the movement of people and goods across space, be it across land or water or through the atmosphere. This unique function inserted transportation as an integral part of regional, national, and international economies since the first days of commercial transactions.

Transport does two basic things for an economy. First, it enables the assembly of material resources and of labor at the sites of production. Transportation is thus pivotal to the successful operation of the supply chains that underpin any economy. Second, transportation enables the dispatch of products to markets. Efficient transportation links to distant potential markets enable a producer to expand output and so enjoy the benefits of economies of scale and divisions of labor.

A way to understand the importance of transportation to the economy is through the notions of efficiency. There are three types of economic efficiency. One is "allocative" efficiency, which is the extent to which resources are allocated to different types of producers in ways that maximize consumer satisfaction over the full range of available goods and services.

Transport plays a crucial role in moving factors of production and final products, sometimes over

Semitrailer trucks may move materials and final products over vast distances in order to sustain economic activity. These trucks were forced to travel through this mountain pass in 2011 in order to bring goods from Pakistan to Kabul, Afghanistan.

vast distances, in order to enable each producer to operate at a level that ensures the best product is made at the lowest possible price.

Another is distributive efficiency. This refers to the extent to which an economy supplies goods and services to those who need them most. Here, the efficiency of transport systems not only enables producers to operate at the necessary production levels but also, importantly, to make final products accessible to disparate groups.

Finally, there is dynamic efficiency, which refers to the capacity of an economy to abandon the production of those goods and services where demand levels are falling in favor of those economic products growing in popularity. Transport plays a major role in both creating awareness of new products and enabling producers to gain access to new sources of supply and to reach new markets.

Of course, transportation systems move people and things for reasons other than for the supply of labor and production materials and the delivery of goods to markets. People also move around

for family, social, and recreational reasons, as do goods. Voters insist, then, that transportation systems be made available to serve a wide variety of objectives, not simply economic ones.

This multipurpose demand on transportation systems creates complex operating environments for different transportation modes. Inevitably, governments and planners must compromise on which transportation systems are possible in the face of extensive demand and limited financial resources.

Role in Overall Economy

Studies of the aggregate impact of transportation on the economy identify two major influences. One is the direct economic effects of the transport sector itself. The value of the transportation sector in advanced economies ranges between about 3 percent and 5 percent of gross domestic product. Another effect is the value that is created by transportation across all sectors of the economy, and here transportation's contribution to gross domestic product is estimated to be around 15 percent to 20 percent.

Positive and Negative Externalities

In addition to the direct benefits of transportation to producers and consumers, transportation creates positive externalities for the economy. This happens in two ways. First, transportation enables the assembly of critical masses of people and, second, it establishes the physical possibilities for these people to enjoy the benefits of being in urban concentrations. These benefits include rising prosperity that comes from expanding levels of production in expanding markets, and the jobs and incomes that are generated.

Yet, providing transport services to concentrations of people in urban areas and their agglomerations of economic activity will necessarily generate undesirable outcomes. Oversubscribed or malfunctioning transport systems mean congestion, rising inefficiency, and higher costs. Negative externalities can also involve unwelcome noise, poor air quality, and unsightly outlooks. While these are not directly paid for any individual producer or consumer, they will affect the cost structures and revenue opportunities of a city's economy into the future because its reputation as a desirable place to invest, live, and work is diminished.

Cost Structures

An important aspect of transport economics involves the analysis of the costs of transport and the ways various costs structures affect transport modes and operation. Every transport mode is differently composed according to the target user group.

A fleet of taxicabs, for instance, is designed to move people on their own or in small groups across short distances in flexible ways. On the other hand, a giant oceangoing ore carrier is designed to move the commodity in large quantities over long repeated distances. Therefore, cars, buses, trains, aircraft, ferries, ships, and so on have different entry costs and different operating costs according to variables such as initial capital outlay, relative fuel efficiency, speed, payload, loading and landing costs, labor costs, and regulatory costs.

In general, large loads carried over long distances involve capital-intensive equipment, but lower variable costs. On the other hand, smaller payloads, for example, 50 people in a metropolitan commuter bus, will incur higher fuel and labor costs but relatively lower capital costs. A major effect of distinctive cost structures across different transportation modes according to distance traveled is to make road travel more competitive over short distances, train travel over moderate distances, and shipping over very long distances.

Land Use Effects

The amenities of residential neighborhoods and the productive efficiencies of commercial and industrial areas are greatly enhanced by the quality of transportation systems that service them. Key here is not just the range and frequency of transportation services but also the extent to which these services are sequenced and synchronized to match the needs of transportation users.

A residential neighborhood, for example, benefits from reliable frequent commuting services during morning and evening peak periods. An industrial area, on the other hand, might need regular servicing 24 hours a day by heavy vehicles and rail services. A consequence of quality transportation services is to raise the value of land in well-served areas. Historically, concentrations of transport services are found in and around urban centers, especially central business districts (CBDs). Frequent passenger transportation services, for example, supply a CBD with workers in the early hours of

the day, and then business clients and shoppers throughout the day.

Access to labor supplies, clients, and customers then makes a CBD a prime location to do business. As a direct consequence, property developers are anxious to erect multistory office towers and elaborate shopping centers, fueling the high demand for office and retailing space in such a CBD. Similarly, the quality of available transportation services significantly affects the land prices in residential and industrial areas and has a major impact on the long-term growth prospects of regional and satellite urban centers.

Transportation and the Disadvantaged

There are two ways in which people who are disadvantaged to some extent—including those who live in poverty, the elderly, people with disabilities, people in minority groups, and women in general—might be considered in the context of transportation studies. The first concerns the transport habits and access to transit of socially disadvantaged groups, and the second concerns how transportation systems (or a lack of transportation) might be responsible for producing and reinforcing disadvantages.

A focus on the “transport disadvantaged” or “mobility deprived” is broadly defined as an inability to get to where one needs to go (for work, school, medical care, etc.) without experiencing difficulty or restriction.

Restriction may result from geographical exclusion, economic exclusion, fear-based exclusion, or lack of physical or mental ability. Studies concerned with the disadvantaged in matters of transportation have made links between transport disadvantage and unemployment, urban deprivation, health care inequality, and underachievement in education.

In making a distinction between social disadvantage and transport disadvantage, it is important to note that the two do not always go together. For instance, it is possible to be socially disadvantaged but have good access to transport, or to be socially advantaged but have poor access to transport. Equally, restricted access to transport does not always equate to transport disadvantage if travel is not a requirement for daily living.

One school of thought views travel problems of disadvantaged groups as an issue that can be adequately addressed through the increased provision of public transport. However, recent studies have argued that access to an automobile is more important than access to public transit in this day and age. This is especially the case with lower-income people who may be dependent upon transportation for employment opportunities.

Lower Income Groups and Welfare Recipients

It is often the case that many disadvantaged groups also fall into the category of lower income. Lower-income groups are likely to be geographically disadvantaged and reside in areas with poor access to transport services. Where access is provided, lower-income people might be priced out of some forms of public transport because they cannot afford it. For example, rapid transport systems (for example, bus rapid transit, light rail, and heavy rail transit) have been viewed as catering primarily for wealthier populations, and, indeed, higher-income people are more likely to use those modes while lower-income people are more likely to use buses.

Because more affluent people are more likely to own cars, they are unlikely to switch to public transit unless the advantages outweigh the convenience of their private vehicles, and these features include the ability to get to and move around cities more

easily and at quicker speeds. A low income is also likely to prevent those groups from accessing private transport, not only private cars, but also taxis and shared-ride services.

Transportation disadvantage is particularly problematic when public transport is not sufficient to fully accommodate the travel needs of the local population. For example, in cities such as Los Angeles, the population is largely dependent upon automobiles for daily mobility, access to services, and access to employment.

In the decades since mass private car ownership has allowed businesses as well as residents to locate to the suburbs, spatial distance often stands between low-income job opportunities (for example, in fast food and retail chains) and low-income residences. Even with access to public transport, commutes from the inner city to the suburbs may be counter to the general flow of commuters from the suburbs to the central business district, leading to slower, less reliable, and more inflexible transportation options, which again negatively affect the employment opportunities of lower-income groups.

The bus is commonly associated with lower income populations. When compared to the autonomy and speed of the automobile, or to the speed and relative comfort of rapid transit, buses are considered to be slower, less secure, less reliable, and less comfortable. In Los Angeles, lower-income groups that are affected by transport disadvantage are more likely to be newly arrived immigrants and ethnic minorities.

Women

Although it is impossible to generalize about the half of the population that is female, there are a number of factors that are likely to lead to the experience of transport disadvantage for women. Women are more likely to have a lower income than men, and are more likely to be responsible for child-care, care of the elderly and people with disabilities, and domestic duties, in general. The need to juggle these responsibilities can have implications for the geographical range that women are able to travel for work, often forcing women to take jobs close to their place of residence, regardless of their skill set and earning capabilities.

Studies have also found that women, like the elderly, are more likely than men to fear for their safety or feel vulnerable on public transport,

Bus commuters on an older-model bus in Lima, Peru, in 2009. When compared to automobiles or to the speed and relative comfort of rapid transit, buses are considered to be slower, less secure, less reliable, and less comfortable. In many places, lower-income people may be priced out of rapid transport systems such as bus rapid transit, light rail, and heavy rail transit. Higher-income people may be more likely to use those modes, while lower-income people are more likely to use buses.

limiting their mobility and the times at which they are willing to travel.

Finally, it is increasingly recognized that the physical differences between women and men should be considered more fully within transport studies, design, and policy. The differences in height, for instance, can make it difficult for women to use overhead racks on trains, while the use of public transport can be difficult when there are limited staff available to help women on and off transport with large or heavy items.

The Elderly

Elderly people are more dependent on public transit than other groups and are often provided with free or highly discounted access. In London, the Freedom Pass allows individuals over the age of 65 to travel for free on a wide network of public transit services. This free access is considered to improve the well-being of the elderly, who are not only dependent on public transport for access to health care and other core services, but for social

networking and other forms of community participation.

Elderly people are also more likely to experience physical difficulties and decreased personal mobility, with slowed reactions and a deterioration of eyesight and hearing. Access to public transport can be physically challenging (for example, no available seats, long and/or numerous flights of stairs, pushing and shoving on crowded vehicles during certain hours, etc.). While most transit systems have elevators to help passengers navigate multiple levels, those services may be difficult to find, dirty, or perceived as dangerous. Similarly, while most public transport systems have designated priority seating for the elderly or disabled, other passengers may or may not honor the priority-seating signage on crowded vehicles.

In addition, fear of large crowds, of falling, or of experiencing difficulties getting on and off vehicles often leads elderly people to avoid public transport.

Paratransit services (such as Dial-A-Ride in the United States or Ring and Ride in the United

Kingdom) are one solution, therefore, for providing door-to-door service for people who find it difficult to use public transport, including the elderly.

Transportation Control Measures

Transportation control measures (TCMs) are a broad class of activities intended to improve air quality by reducing emissions from vehicles used for transportation and to reduce fuel use by encouraging energy-efficient means of transportation. Examples of TCMs include improving public transit and pedestrian and bicycle facilities so that those means of transport replace some automobile traffic, encouraging employers to offer flexible schedules so fewer people are on the road at peak traffic hours, and fostering the creation and use of shared-ride services so that fewer single-occupant motor vehicles are on the road, particularly during peak hours. In the United States, a number of TCMs are specified in the Clean Air Act, and TCMs

receive highest priority for funding under the Congestion Mitigation and Air Quality Improvement (CMAQ) Program.

Background

Transportation accounts for 33 percent of carbon dioxide (CO₂) emissions and produces numerous other toxic pollutants that are dangerous to human health. TCMs are activities that attempt to change aspects of present transportation practices to reduce these harmful effects.

Section 108 of the Clean Air Act, as amended in 1990, lists 26 activities that qualify as transportation control measures, including improved public transit, creation of high occupancy vehicle (HOV) lanes, improving access for pedestrians and cyclists, creating measures to curb extended vehicle idling, and creating programs to encourage voluntary removal of pre-1980 vehicles from the roads and the marketplace.

Specific programs can also qualify as TCMs if they are committed to in State Implementation Plans (SIPs) or will reduce transportation-related emissions by fostering improvements in traffic flow or reductions in vehicle use.

The Intermodal Surface Transportation Efficiency Act (ISTEA), passed in 1991, funds transportation projects and programs intended to assist regions in meeting ambient air quality standards. The CMAQ Improvement Program was established under ISTEA, and CMAQ is apportioned to states that then allocate funds within the state.

CMAQ projects are intended to produce measurable reductions in dangerous emissions products, including particulate matter (PM), nitrogen oxides (NO_x), carbon monoxide (CO), and volatile organic compounds (VOCs). However, for purposes of evaluating the effects of a TCM program, results can be described in terms of changes in travel patterns (for example, reduced person-trips or time of day of travel), reductions in vehicle activity (for example, total vehicle trips or total vehicle miles of travel), changes in traffic flow characteristics (for example, travel speeds), and changes in vehicle activity and traffic flow resulting in changes in emissions.

Public Transportation

One major class of TCMs involves encouraging the use of public transportation by providing available, affordable, convenient, and reliable services, and

using public information campaigns to make the population aware of the services available and the benefits of using public transportation. Examples of programs to encourage transit use include the creation of dedicated bus lanes to speed travel, park-and-ride facilities, and discount-fare or other incentive programs, as well as upgrading transit vehicles and shelters. The use of public transportation reduces emissions and fuel use, while also reducing congestion and improving traffic flow. Transit may also provide a better experience to the rider. For example, it is possible to read while riding the bus or train, and it is not necessary to pay attention to the road.

Transit-oriented development (TOD) encourages both the use of public transportation and the development of neighborhood-scale developments that can be traversed on foot. The concept behind TOD is to encourage development of mixed-use centers near transit stations; such developments may include housing and a variety of commercial entities, including shops, restaurants, and entertainment sites such as movie theaters and nightclubs near transit stations.

People who live in such areas can meet many of their daily needs (for example, grocery shopping) on foot, while using public transportation if they need to make a longer trip. Visitors can use public transportation to reach the area and access the facilities within it on foot. TOD reduces emissions and fuel use by reducing the use of private cars and also provides a pedestrian-oriented experience that many people enjoy.

Complete Streets

“Complete Streets” programs encourage pedestrian and bicycle transportation and the use of public transportation by making it safer and more pleasant for people to walk, ride bicycles, and use public transit. The name means that streets are for everyone, not just motorized vehicles.

Examples of Complete Streets measures include creating bike lanes, improving street and sidewalk lighting, providing bicycle racks and showering/changing facilities for cyclists, changing zoning laws to encourage mixed-use development, and providing wide and conveniently spaced crosswalks for pedestrians. Encouraging alternative forms of transportation reduces emissions and fuel use, and also facilitates a variety of experiences not possible in automobile-oriented environments.

Commuter Options

Creating new options to expand commuter choices encourages people to use transportation options other than treating driving as the default transportation solution. Some are best implemented directly by the government; one example is building park-and-ride lots to reduce traffic into the city center. Others may be better implemented by employers, although governments can provide incentives for the adoption of these programs (and, of course, governments are also employers themselves).

Examples of the second type of program include carpool and vanpool services, including rider matching; provision of preferred parking spaces for pool vehicles and financial incentives for employees to use a carpool or vanpool to commute to work; subsidized transit passes, possibly coupled with increased parking fees, to encourage employees to use transit rather than driving to work; and guaranteed ride home services, which provide emergency transportation to those who normally use public transportation or shared-ride programs and may need transportation after hours. These programs may save the employer and the city money by reducing parking space requirements, congestion on roads, and emissions and fuel use.

Telecommuting programs allow employees to work at home one or more days per week, thus eliminating the need to drive to and from their usual workplace. By taking some commuters completely out of the transit marketplace for at least part of the workweek, telecommuting reduces the load on the entire transit system. In addition, employees save the time they would have spent commuting, and employers do not have to provide parking for the days the employees work from home.

Sometimes combined with telecommuting, workplace flexibility programs allow employees some flexibility in the days and times in which they work. These programs reduce the strain on the transit system by allowing employees who commute to work to avoid peak hours of travel, thus reducing travel time and congestion as well as reducing emissions and fuel use. Nonstandard scheduling may have a similar effect. For example, some government offices have spread a 40-hour week over four days (10 hours per day) rather than five, thus reducing by one the number of days an employee needs to commute to work and also

shifting the hours employees commute away from peak periods of travel.

Other Approaches

Incident management systems focus on reducing traffic congestion by quickly clearing stalled or crashed vehicles from the road. Incident management systems are generally applied to highway systems and include the creation of roving tow and service vehicles, as well as a system of motorist call boxes or dedicated phone numbers to call for aid.

Value pricing systems force drivers to pay the full cost of services they consume and thus encourage the use of alternative forms of transportation. For instance, instead of offering subsidized parking, companies could be encouraged to price parking at its true cost. Congestion pricing is a similar concept; by charging motorists more to drive into an area or to park during the hours when demand is highest, drivers are encouraged to find other means of transportation or to make nonessential trips during nonpeak traffic periods.

Transportation Cooperative Research Program

The need to meet expanding mobility, environmental, and energy demands in the United States has placed a heavy burden on the nation's public transportation systems. Existing public transit systems increasingly must find ways to expand services, improve efficiencies, and evolve aging fleets. These activities require a sound foundation in research in order to effectively address operating issues, apply new technologies, and deliver innovative solutions to meet today's transportation requirements.

The Transit Cooperative Research Program (TCRP) was established under the Federal Transit Administration (FTA) in 1992 to help the U.S. transportation industry accomplish those goals by providing transit research in the areas of policy, planning, equipment, services, operations, administration and maintenance. The TCRP's research reports provide comprehensive but concise information that transit professionals and agencies use to solve transportation-related problems, implement innovations, streamline processes, optimize resources, and reduce costs.

Program Participants

The FTA sponsors the TCRP, which received \$6.5 million in federal funding for research in fiscal

year 2012. Operations of the research program are managed by the TCRP Oversight and Project Selection (TOPS) Committee with the administrative support of the Transportation Research Board (TRB), a unit of the National Research Council of the National Academies. The TCRP's research is conducted with the assistance of state and local government officials, transportation industry professionals, transit equipment and service providers, and diverse research organizations. The American Public Transportation Association (APTA) acts as the program's liaison with the transit community.

Each research project is assigned to a dedicated panel appointed by the TRB that is responsible for providing technical guidance throughout the project's life cycle. The panels are comprised of voluntary members who are industry professionals and researchers and, when possible, represent in some way the project's targeted demographic. The panel members draft the specific project statements and select contractors based on their proposals submitted through an open process that enables all research agencies to compete for the project work based on their technical merit. The process ensures that the TCRP has access to the best talent available for each project.

In selecting contractors to work on the TCRP's research projects, the panel members evaluate submitted proposals according to six key criteria: demonstrated understanding of the research problem; merit of the proposed research methodology and design; demonstrated experience, qualifications, and objectivity in the same or similar research area as the project; specified plan for the application of research results; inclusion of small business enterprises owned or controlled by women or minorities; and adequacy of research facilities. The panel also considers potential sources of bias and conflict of interest among contractor candidates that might jeopardize the integrity of the research activity and final report.

Once a TCRP report is completed, the primary objective of the program is to disseminate the results to the intended end users of the research, such as transportation agencies, service providers, suppliers, and other interested parties. The APTA has the lead role in ensuring that the TCRP research results are made available to the relevant constituents via conventional channels, as well as through more interactive means. The APTA conducts field

visits, workshops, training, and other activities to disperse the TCRP results and facilitate understanding and action by transportation industry professionals.

Areas of Research

Anyone can submit a request for TCRP research to the TRB at any time. Requests are evaluated by the TOPS committee to ascertain research scope, required funding levels, and expected outcomes. Each request is then prioritized based on how well the research aligns with and supports the strategic research goals of the TCRP and the FTA. The strategic goals are focused on two key areas: increasing livability for American citizens and improving the performance of transit operations and systems in the United States.

In the area of increasing livability, the FTA conducts research aimed at helping transit agencies enhance transportation services in their communities. Types of research that would come under this strategic category vary widely. Examples include projects that help determine infrastructure improvements that could be utilized to enlarge transit capacity, projects that help identify cost-assessment tools that could be used to illustrate financial impact of ridership levels, and projects that investigate new technologies, marketing approaches, or capacity innovations.

In regard to improving the performance of transit operations and systems, the FTA focuses on research that supports the accessibility, reliability, efficiency, safety, and affordability of public transportation for all individuals throughout the United States. Research in this area might address technologies and approaches that can improve the planning, design, construction, management, maintenance, and utilization of transit systems and that maximize transportation investment dollars while reducing risks and uncertainties.

Safety, mobility, and sustainability research also fall under the FTA's performance improvement goal. This type of research might include methods to improve emergency preparedness among transportation organizations and professionals, reduce transit-related emissions and energy dependence, or increase access to transportation services for the disabled, the disadvantaged, and the elderly.

Within the strategic framework set by the FTA, the TCRP has its own set of objectives and priorities

that reflect the organization's principles and direct its actions. Foremost, the TCRP has committed to placing transit customers first, followed very closely by the community as a whole. The rationale is based on the belief that the transportation industry cannot prosper if it fails to meet the changing and expanding demands of the U.S. consumer.

The TCRP also strives to support the integration of advanced technologies into all aspects of public transportation to ensure that changing mobility needs among consumers and within communities are appropriately met. More broadly, the TCRP has pledged its ongoing support to improving public transit systems and experiences throughout the nation via continuous development and enhancements.

The organization also recognizes the expanding role state and local officials have in setting and allocating transportation funding dollars. As a result, the TCRP has made it a goal to help the transportation industry work more collaboratively with government and community programs to optimize opportunities related to community planning initiatives and intermodal transit (that is, transportation by more than one means of delivery). The fifth and final stated goal of the TCRP is focused on revitalizing transit organizations themselves to take best advantage of information technology progression, workforce evolution, and new roles and alliances within the transportation industry as a whole.

Synthesis Program

In addition to its cooperative research reports, the TCRP also encompasses several subprograms designed to support transportation-related research and facilitate sharing of transit-focused information. The Synthesis Program, for example, is dedicated to amalgamating the best available knowledge about topics of concern to the transportation industry. To ensure the inclusion of significant and relevant knowledge, the program taps numerous sources that serve as a storehouse of information regarding transit concerns. A great deal of the warehoused information is the result of prior research and real-world application of solutions among transit industry professionals.

While the knowledge readily exists, there was a lack of a formal channel for compiling and sharing the data until the TCRP implemented the Synthesis of Transit Practice report series as part of the Synthesis Program. Under the program, the TCRP

collects and assembles the various forms of information into concise reports pertaining to specific transit problems and associated issues and makes recommendations for action where appropriate.

Transit IDEA Program

The Transit IDEA (Innovations Deserving Exploratory Analysis) Program is another subprogram of the TCRP. It provides start-up funding for innovations in surface transportation systems that would be unlikely to receive financial backing through conventional sources. The program is primarily focused on research that is dedicated to finding ways to increase transit use; improve transportation safety, security, and emergency preparedness; increase transit capital and operating efficiencies; and promote environmentally friendly transportation practices, such as increased energy independence.

Since 1994, the TCRP has sponsored an International Transit Studies Program (ITSP) aimed at expanding the professional development of U.S. transportation professionals by providing them with opportunities to learn from transit systems in other countries. The intent is that those professionals will return to the United States with new perspectives and knowledge that could be applied within their own organizations and among their peers across the country.

The IDEA program sponsors two international study missions annually in which teams of U.S. public transportation professionals visit successful transit operations abroad. Each study mission lasts for two weeks and centers on a key issue of concern in public transportation. The locations for the site visits are chosen based on the host company's ability to illustrate new concepts or innovative approaches to addressing the public transportation challenges outlined in the IDEA study mission.

As part of the program requirements, each participant—selected on the basis of an open nomination process—must prepare a trip report upon return that speaks to an element of the mission agreed to in advance by the IDEA group. The participants' reports are consolidated into a single mission report for TCRP publication and distribution to transportation industry professionals.

Other Subprograms

The TCRP's Legal Research Digest Program researches and reports on issues tied to

transportation and intermodal law. The reports are designed to provide transit attorneys with reliable, targeted information about environmental standards and requirements; construction and procurement contract procedures and administration; civil rights and labor standards; and liability, risk management, and system safety issues having national significance to the transit industry.

An additional subprogram of the TCRP includes the Quick Response for Special Needs Program, which is a specially funded program that provides a mechanism for responding rapidly to research problems that require swift or immediate attention based on the assessment of a TOPS task force.

All the TCRP's programs combine to provide an invaluable resource for the U.S. transit industry. According to an awareness and advantages survey performed by the TCRP at the end of 2002, the majority of respondents (85 percent) considered the Transportation Cooperative Research Program to be beneficial, both individually and industry-wide. Comments solicited from respondents revealed that the TCRP's research was used extensively by industry professionals. The respondents indicated that the TCRP's research had helped them to significantly reduce the time, cost, and staffing resources needed to obtain important background information on transit issues, and that they used the TCRP research to support decision making and training.

Approximately 20 percent of respondents also reported direct cost savings totaling nearly \$13 million as a result of using the TCRP's information reports and research services. As of May 2013, the TCRP had published more than 600 research reports to benefit the U.S. transportation industry.

Transportation Equity Act for the Twenty-First Century

The Transportation Equity Act for the 21st Century (TEA-21), passed in May 1998, largely kept the provisions made by its predecessor, the Intermodal Surface Transportation Efficiency Act (ISTEA), for federal transportation legislation concerned with providing funding flexibility to states and encouraging balanced investment in highway, transit, intermodal transportation, and technological projects to ensure integrity of all transportation systems in the United States.

Among TEA-21's important changes from ISTEA were the guaranteed funding of Highway Trust Fund (HTF) revenues for surface transportation, guaranteed 90.5 percent return to states on revenues paid into the HTF, the continuation and expansion of environmental programs created by ISTEA, strengthening of planning requirements, expansion of the flexible funding provisions, and a stronger emphasis on safety. The major debates surrounding TEA-21 centered on fair distribution of funds among states and the appropriate size of federal support. Delays in passage, a highly partisan process, and a greater degree of earmarking than previous legislation marked the legislative process.

The Legislative and Political Process

ISTEA, the omnibus federal funding legislation originally passed in 1991, was set to expire on

October 1, 1997. By late 1996, discussion of the next transportation bill largely concerned distribution of federal funding for the states. In 1995, the returns per dollar contributed to the HTF varied from 56 cents in South Carolina to \$6.40 in Alaska. “Donor” states argued for overhauling ISTEA funding formulas to give them a fairer share. While most recognized that heavily rural states lacked the population density to fund their highway systems fully, many argued that the range should be narrowed.

The STEP 21 coalition (representing 21 states) wanted to adjust ISTEA formulas to guarantee 95 cents return per dollar contributed the HTF and to consolidate most ISTEA programs into a block grant to allow states even greater spending flexibility. A smaller coalition of states argued for devolution of almost all highway and mass transit policy to states.

Meanwhile, the Alliance for ISTEA Renewal, a group of mayors, county governments, city governments, metropolitan planning organizations (MPOs), and the Surface Transportation Policy Project, argued for minimal changes from ISTEA. On the other hand, oil, automobile, and trucking companies lobbied to increase state government officials’ power in project selection via a flexible block grant.

President Bill Clinton’s proposal, the National Economic Crossroads Transportation Efficiency Act (NEXTEA), called for a \$175 billion, six-year plan that largely retained ISTEA’s objectives. However, in Congress, efforts to negotiate federal transportation legislation collided with the Republican Budget Committees’ promise to balance the federal budget by fiscal year 2002. Their agreement to only \$125 billion funding over five years generated opposition from both House and Senate Transportation Committees, who were in the process of working on their respective bills.

Following months of deadlock, both committees passed bills exceeding agreed budget spending limits in September 1997; however, Senate filibustering over campaign finance reform left insufficient time to deal with the transportation legislation during the year’s final session. Both houses agreed to extend ISTEA through May 1, 1998, through a reauthorization called the Surface Transportation Extension Act of 1997 (short-TEA).

Following the post-recess announcement that higher-than-anticipated revenues would mean a

projected budget surplus, both houses passed bills with larger funding proposals: the Senate’s ISTEA-II and the House’s Building Efficient Surface Transportation and Equity Act (BESTEA).

TEA-21, the reconciled bill that emerged from conference, comfortably passed both houses of Congress on May 22 and became law on June 9, 1998. Because of errors made in the rush to pass the legislation before the Memorial Day recess, technical corrections known as the TEA-21 Restoration Act were made and voted into law shortly thereafter.

Content and Implementation

TEA-21 authorized approximately \$218 billion in total transportation spending over six years (fiscal years 1998 through 2003) with \$167.1 billion designated for highways and \$36.3 for mass transit. It also continued all the major ISTEA programs and added a number of new programs to meet specific safety, economic, environmental, and community challenges.

TEA-21 retained ISTEA’s core spending category structure. The five major funding mechanisms under the Federal Aid Highway Program included the National Highway System (NHS), the Interstate Maintenance (IM) system, the Surface Transportation Program (STP), the Bridge Replacement and Rehabilitation (BRR) program, and the Congestion Mitigation and Air Quality (CMAQ) program. Most mass transit funding was in the form of grants, the largest of which was the Urbanized Area Formula (UAF) Grant.

The \$28.5 billion funding for the National Highway System (NHS) accounted for about 13 percent of TEA-21 funding. These funds could be used for the major highway system, including the interstate system and principal arterial roads designated as necessary to the national economy and defense.

The formula allocating these funds among states included state percentages of NHS non-interstate lane miles, vehicle miles traveled, diesel fuel, and population. The approximately 11 percent of TEA-21 funds allocated to the IM program was for exclusive use on the interstate system. The 15 percent of TEA-21 funds allocated for the STP could be used flexibly for projects including roads, intermodal infrastructure, environmental improvements, research, or planning. The BRR and CMAQ programs were funded at \$20.4 billion and \$8 billion, respectively. BRR funds could be used for any

bridge on a public road. CMAQ funds, distributed based on the percentage of a state's residents living in polluted areas, could be used for any project intended to meet air quality standards.

Two of the most significant achievements of TEA-21 were the guaranteed funding and the continuation and expansion of environmental programs created by ISTEA. TEA-21 also strengthened the planning requirements, expanded the flexible funding provisions, and placed a stronger emphasis on safety.

TEA-21 created a "firewall" around the HTE, changing the rules to ensure that its spending would be separate from general defense and discretionary spending categories. With this firewall, reduced spending for transportation could not be used to increase spending for other domestic discretionary programs, thus eliminating the principal incentive for reducing transportation spending.

The firewall amount linked directly to projected receipts into the HTE, guaranteeing specific amounts of funds to be spent on surface transportation and transit. Furthermore, to meet the demands for better spending equity, TEA-21 guaranteed states 90.5 percent return on revenue paid into the Highway Trust Fund.

To add a stronger environmental emphasis, TEA-21 created a new program, the Transportation and Community and System Preservation Pilot Program, to support planning for environmentally friendly development by states and localities. The key purpose of this program, created in response to increased interest in smart growth, was to devise innovative neighborhood, local, metropolitan, state, or regional strategies that would improve the efficiency of the transportation system, minimize environmental impacts, and reduce the need for costly public infrastructure investments. TEA-21 also created an environmental streamlining pilot program to reduce red tape and paperwork in project reviews without compromising environmental protections.

TEA-21 did not heed the highway lobby's pressure to decrease MPO and local officials' power relative to state transportation agencies. Rather, TEA-21 retained the general structure of the planning process for metropolitan areas and states as enacted by ISTEA, but streamlined the planning processes and specifically included freight shippers as stakeholders in the planning process. To streamline the planning process, TEA-21 consolidated the

16 factors and criteria used in project planning into seven broad factors. TEA-21 also retained the fiscal constraint provision of ISTEA.

TEA-21's substantial changes for safety programs included increased funding for safety, greater flexibility in using categories of funding for a wide variety of safety-related efforts, new programs to promote seat belt and child safety seat use, and tough new measures to target repeat drunk drivers and to ban open alcohol containers in cars.

TEA-21 created a \$500 million Safety Incentive Grant for which states enforcing a 0.08 blood alcohol concentration limit would be eligible. One of the seven new planning criteria was safety and security for both motorized and nonmotorized users, which brought pedestrian and bicycle safety features into more prominent focus.

Furthermore, the railway-highway crossing program opened hazard elimination measures to a broader range of infrastructure, including interstate highways, public transit facilities, and bicycle or pedestrian pathways. The act also restructured the Motor Carrier Safety Program to allow states flexibility in tailoring commercial motor vehicle safety solutions to meet their individual needs.

Beyond these major changes, TEA-21 had other substantive provisions and impact. Two new programs, the border crossings and trade corridors programs, were intended to ensure the country's continued transportation advantage and allow it to compete effectively in the global arena. These programs would support trade, improve border security, and facilitate the design and construction of corridors of national significance.

A new State Infrastructure Bank pilot program was created under which four states (California, Florida, Missouri, and Rhode Island) were authorized to enter into cooperative agreements with the federal Department of Transportation to set up infrastructure revolving loan funds. The Transportation Finance and Innovation Act of 1998 created a new \$530 million credit assistance program to help leverage \$10.6 billion for construction of projects of national importance, such as intermodal facilities, border crossing infrastructure, and expansion of multistate highway trade corridors.

Legacy

TEA-21 largely continued the momentum from ISTEA's policy changes. TEA-21's successor, the

Safe, Accountable, Flexible, Efficient Transportation Equity Act: A Legacy for Users (SAFETEA-LU) continued this policy emphasis shift from building and maintaining highways toward managing a performance-driven, intermodal system.

With TEA-21, states were given a higher degree of flexibility and had the opportunity to make revolutionary changes to their transportation spending patterns. While in the early years of TEA-21 implementation, the trend away from using federal funds for new highway construction and toward maintenance and intermodal projects appeared to be reversing, scrutiny revealed that much of the escalation in new highway spending came from just one project, the “Big Dig,” Boston’s Central Artery/Tunnel Project.

The late 1990s TEA-21 implementation period represented one of only a few periods when mass transit use in the United States grew faster than automobile use. Federal spending on pedestrian and bicycle infrastructure, while remaining small compared to the overall program costs, also increased from less than \$7 million per year before ISTEA to over \$400 million in 2003.

ISTEA and TEA-21 also remarkably increased spending on transportation planning and administration, more than tripling it in the 1990s. These costs directly relate to the new planning requirements that greatly expanded the number of stakeholders involved in decision making, broadening participation beyond the previous structure of a small number of engineers, contractors, and government officials.

Transportation Impact Analysis

Transportation impact analysis (TIA), also known as traffic impact analysis, is a type of engineering study used as a tool to determine potential surface traffic impacts of a proposed development. The complete analysis can be used to forecast future effects from existing and proposed development projects and to predict the useful life of a transportation project across expected future land use scenarios. These studies are also used to help evaluate whether a proposed development is appropriate for a site and what type of transportation improvements may be necessary.

Significance and Process Components

Better decisions can be made when impacts are accurately projected through the traffic analysis process. Mindful planning results in less future traffic congestion, fewer safety issues, milder environmental impact, and avoidance of unnecessary and costly improvements.

The major elements of a TIA include existing conditions analysis, estimation of future traffic with and without development, analysis of traffic impacts, and recommended roadway improvements. A number of variables are involved in, and data collected for, the assessment, depending on the type, size, and location of development proposed. These typically include trip generation rates, trip distribution, peak morning and evening traffic flows, intersection capacity, vehicle demand, turning movements, and mitigation.

Some impact studies include data on transit, pedestrian, and bicycle traffic, as well as on parking, freight loading, and construction activities.

Depending on the municipality and state in which the development is proposed, specific process guidelines are available for developers and transportation authorities.

Examples and Models

The study area of a site is determined and the project setting and description are compiled. These include existing and proposed total gross square footage for each land use type, description of existing transportation infrastructure, and description of change in function of lanes, public rights-of-way, and access sites. The initial overview should identify study issues, needs, assumptions, procedures, available sources of data, past and related studies, report requirements, and other topics relevant to prepare the analysis.

Other considerations during the overview phase of any development project are horizon year of buildout related to the proposal; other developments currently approved or under way; number, locations, capacity, and safety issues related to access points; and potential mitigation opportunities.

After the initial information is compiled, a travel demand analysis and traffic impact analysis need to be performed. Data collection and interpretation will usually include trip generation and distribution rates. Trip generation (simply put: in-and-out traffic) is the estimate of daily person-trips for an average weekday generated by households within each study area.

The *Trip Generation Manual* published by the Institute of Transportation Engineers (ITE) is often used as a guide and handbook to calculate these rates. Mainly, estimates are determined by data on weekday morning peak-hour and weekday evening peak-hour trips in residential areas.

There are typically two types of use for trip generation rates: (1) a transportation planning process that involves large zones of urban areas, with a goal to forecast the number of trips that will begin from or end in each travel analysis zone (TAZ); and (2) planning or forecasting based on trips made to a particular land use site, with a goal to determine impact of development, or land use changes.

For transportation planning, zonal trips are estimated for a variety of trip purposes: work trips, school trips, shopping trips, and social or recreational trips. Models may be zonal or household based. Person-trips may include pass-by trips

(trips attracted from existing traffic on adjacent streets), such as stops made at banks, service stations, and convenience stores; and link-diverted trips (trips produced from the traffic on roadways within the vicinity of the generator, and require a diversion).

Trip distribution is a model of the number of trips that occur between each origin zone and each destination zone, estimated by trip generation data. Trip distribution models strive to predict the number of trips that will be made between a pair of zones for a particular trip purpose.

There are various models of trip distribution. However, most of the models incorporate the same basic factors that affect the number of trips between an origin zone and a destination zone. The factors are: the number of trips produced by the origin zone, the degree to which the attributes of the destination zone attract trip makers (attributes that gain importance vary with the trip purpose), and the factors that inhibit travel between a pair of zones. These factors could be travel time, travel distance, and travel cost.

After data are collected and analyzed for traffic demand and impact, other existing information is added to the compilation: roadway and intersection geometrics such as roadway width, number of lanes, lane configuration at intersections, and channelization; accident data; traffic control device inventory such as signal timing and phasing, stop signs, and yield signs; and land use code(s) selection and application.

Level of service for signalized and nonsignalized intersections should be in accordance with the latest edition of the *Highway Capacity Manual* published by the Transportation Research Board (a division of the U.S. National Research Council).

New Strategies

The technical methods to estimate how much traffic a new development will create have been standardized and are used by traffic engineers across the country. These methods are generally based on data collected from single-use, automobile-dependent, suburban sites. They do allow for some internal capture (trips that might be entirely within larger, mixed-use developments), but in general the methods do not adequately account for the effects of compact development, mix of uses, site design, walkability, transit, or regional accessibility, which

are all key elements of smart growth strategies and sustainable communities.

Recent research has shown that neighborhoods that mix land uses and that are near other developments allow residents and workers to drive significantly less if they choose. Research also shows that in the most centrally located, well-designed neighborhoods, residents drive as little as half as much as residents of outlying areas. An added benefit is that pedestrian and biking traffic tend to be safer. Along with these benefits, mixed-use development can improve communities in other important ways, including supporting affordable housing by lowering transportation costs for residents.

Currently, leading researchers and practitioners in transportation and development are designing new methods to estimate traffic impacts of mixed-use developments. They are looking at how various land use factors such as density, regional accessibility, and roadway connectivity affect travel behavior, including per capita vehicle travel, mode split, and nonmotorized travel. The goal is to achieve planning objectives such as consumer savings, emission reductions, improved public fitness and health, and habitat protection, all allowing for smart urban growth.

Transportation Impacts on Land Use

Land use refers to the human use of land, which can be described from two perspectives: functional, which is concerned with social and economic activities taking place at the specific geographic location, and formal, which is concerned with the spatial pattern. The functional perspective is to segregate use categories that are thought to be incompatible, such as residential, commercial, institutional, industrial, agricultural, forests, or parkland. The formal perspective can be evaluated using such attributes as density, clustering, mix, and connectivity.

Transportation impacts land use, both functionally and formally. Reliance on auto use, commonly seen in the suburban areas in the United States, contributes to low-density and expansive land development, as well as the segregation of different land use types. Convenient and reliable transit service allows a nodal urban form and often leads to high-density and mixed-use development. Pedestrian and bicycle facilities implemented in many cities—such as bike lanes, improved sidewalks, and

bike sharing programs—encourage walking and cycling, fostering pedestrian-oriented retail and service development.

The interaction between land use and transportation has long been recognized. Their relationship is often described as a chicken-and-egg problem because the causal links between transportation and land use tend to be intertwined. Land use changes travel demand, remolds accessibility, and thus influences transportation. Transportation, in turn, influences land price and shapes land use development patterns.

Although the effects of transportation on land use are largely moderated by long life cycles of land development and durable real estate stock, the impacts of transportation on land use over time are evident: transportation consumes land and shapes land development. In general, slow travel modes lead to the formation of dense city cores and the popularity of cars results in dispersed development.

Mobility Versus Accessibility

Mobility and accessibility are two key concepts used by transportation professionals when explaining the relationship between transportation and land use. These two concepts are similar because both measure transportation cost, which is an important factor for location choice. Households balance the money and time spent on their daily trips to work, shopping, and recreation with housing costs and other amenities. Firms seek lower transportation costs for their connections to suppliers, consumers, and employees. However, mobility and accessibility are significantly different concepts, and this has led policy makers to completely different notions in transportation planning.

Mobility measures the physical movement of people and goods and emphasizes the level of service of transportation systems, mainly focusing on the improvement of transportation supply. For professionals largely focused on improving mobility in the last century, the emphasis has been on transportation supply. As a consequence, significant increases in road and parking capacities have been observed. This has led to dispersed land use patterns.

In contrast, accessibility considers the ease or difficulty of desired goods or services to be reached, implying a more holistic consideration

of land use and transportation systems. In recent years, accessibility has gradually been adopted by more practitioners. Examples of efforts to improve accessibility can be seen in several cities. With mixed-use land development and the integration of multimodal transportation, planners are able to control urban sprawl and revitalize city cores.

Direct Impacts Versus Indirect Impacts

Transportation affects land use, both directly by consuming land for transportation facility development, and indirectly by changing accessibility and influencing land development. In a recently updated report, researchers carefully examined the impacts of transportation on land use. As far as direct impacts, an estimated 0.7 percent of the continental United States is devoted to road rights-of-way, and 0.4 percent of the land is paved for roads. In addition, parking facilities cover a big portion of urban land, especially in commercial use.

The development of transportation facilities requires a change in land use to provide space for transportation construction. At the same time, land development relies on transportation supply, such as transit for apartment towers, parking lots for shopping malls, and transfer hubs for factories. These direct impacts between land use and transportation are easy to recognize.

In contrast, it is often hard to quantify transportation's indirect impacts on land use, especially in the long term, because changes in transportation conditions are often intertwined with changes in the economy, population, and other facilities. Each system is complex and dynamic, making it difficult to assess the exact land use impacts of a particular transportation project. Researchers and practitioners often resort to land use models for such assessments, and those models can capture some but not all effects. The overall assessment, therefore, must be based on a combination of modeling and professional judgment.

Urban Land Use Models

Many studies have been conducted in attempts to assess the interaction between land use and transportation. With the aid of this research, practitioners have been able to partially understand the impact of transportation policies and programs on land use. However, as some researchers concluded in a review of existing land use/land cover models,

no single land use model has yet successfully captured all the effects.

Some approaches are more common than others and they already have been used in the integrated models of land use and transportation. Examples include T. de la Barra's TRANUS (1989), J. D. Hunt and J. E. Abraham's PECAS model (2005), K. C. Clarke's SLEUTH model (2007), and P. Waddell's UrbanSim (2002). TRANUS and PECAS are both aggregate models with zones (typically census tracts or traffic analysis zones) as their observational units. They recognize spatial effects by controlling for results from a spatial input-output model. These models are more appropriate for examining the impacts of transportation policies on a macro level (for example, state or national level).

The cellular automata-based SLEUTH model consists of an Urban Growth Model (UGM) and Deltatron Land Use/Land Cover Model. SLEUTH simulates land cover change by recognizing the temporal and spatial context of each cell, but it only shares information across immediately adjacent cells. More dispersed interactions and correlations are largely ignored.

In addition, by relying on a rule-driven algorithm, SLEUTH is not designed to flexibly accommodate the effects of many influential human factors. Therefore, SLEUTH is more appropriate to simulate and predict land use changes without complex economic interactions, such as deforestation and desertification.

UrbanSim is currently the most widely adopted land use model. As an agent-based simulation system, UrbanSim can use grid cells or user-defined zones as its observational units. The land development modules in UrbanSim largely rely on standard, multinomial logit specifications to handle the discrete nature of land use type. The model controls for regional, neighborhood, and cell characteristics to diminish spatial effects.

Implication for Policy Makers

Given the influence of transportation on land development, public agencies have the power to induce land use change by providing infrastructure and implementing transportation-related policies. Many transportation developments and policies, such as road pricing, have caused significant changes in land use development, intentionally or unintentionally.

Seeing such connections, the U.S. Congress mandated that planning organizations consider the potential effects of transportation on land use through the Intermodal Surface Transportation Efficiency Act (ISTEA), which requires that transportation plans and programs be designed consistently with short-term and long-term land development plans. Later on, the Safe, Accountable, Flexible, Efficient Transportation Equity Act: A Legacy for Users (SAFETEA-LU) reconfirmed the requirement for all federally supported transportation plans and programs to consider land use.

The act states that they must "protect and enhance the environment, promote energy conservation, improve the quality of life, and promote consistency between transportation improvements and state and local planned growth and economic development." The Moving Ahead for Progress in the 21st Century Act (MAP-21), the latest federal law on transportation planning and policy, continues to emphasize the importance of integrated consideration of transportation and land use.

Emerging Issues

The development of technology and changing lifestyles in recent years have led to disputes over whether the impacts of transportation on land use are diminishing. For example, increasing telecommunication and online shopping make it easier for people to work, shop, and access amenities without explicitly paying for transportation. The perception that transportation costs have been eliminated in such situations may alter people's and firms' location choice behavior, reshaping urban land use patterns.

Most cities today already have large transportation capacity and real estate stock, moderating the impact of transportation changes on land use. In such a situation, a marginal change in transportation may not have an evident effect on land use. In short, as urban systems become more complex, these investigations of transportation's impacts on land use are becoming more challenging.

The TIP lists specific priority projects, financial allocations, and a tentative schedule of projects. The TIP is required by federal law (Moving Ahead for Progress in the 21st Century, or MAP-21, as of 2013) to receive and spend federal transportation funds and must cover at least the next four years. Every dollar spent by government agencies must undergo thorough scrutiny to ensure that the spending will provide benefit to the society.

The TIP allows federal, state, regional, and local government agencies to carry out such a scrutiny before consideration for funding. The TIP is developed by a collaborative process and ensures conformity with national air quality standards and state transportation improvement plans.

Need for the TIP

The U.S. federal government distributes funds to states and metropolitan areas based on the federal transportation law. Per federal law, every metropolitan area in the United States with more than 50,000 in population must have a metropolitan planning organization (MPO) responsible for preparing the Long-Range Transportation Plan (LRTP) and the TIP.

While the 20-year-horizon LRTP provides a vision for the transportation improvements for the region based on economic, land use, and demographic projections, the TIP provides a list of projects that are consistent with that vision. It is expected that the projects in the TIP will lead to the implementation of the vision put forward in the LRTP. It should be noted that the TIP represents an agency's intent to construct or implement a specific project and the anticipated flow of federal funds and matching state or local contributions. It is not a commitment.

Transportation Improvement Programs

The Transportation Improvement Program (TIP) is a financial program that describes the schedule for obligating U.S. federal funds for transportation to state and local projects such as highways, bridges, transit, freight, and nonmotorized transport such as bike and pedestrian improvements. It also includes set-asides for programs such as safety and intelligent transportation systems (ITS).

Contents of the TIP

The TIP lists all projects that intend to use federal funds, along with nonfederally funded projects that are regionally significant. The TIP can also include other state-funded capital projects, which are not required but are often shown for information purposes.

The TIP not only lists the specific projects but also documents the anticipated schedule and cost for each project phase (for example, preliminary engineering, final design, right-of-way acquisition, and construction). The projects in the TIP are expected to be implemented during the TIP period.

Bridge maintenance can be challenging, as there are only a few accurate techniques to test for integrity and safety. The Transportation Improvement Program (TIP) allots the scheduling of federal funds to projects such as maintaining or improving existing bridge infrastructures.

Time Span and Update

The list of projects in the TIP must be financially constrained to the amount of funds that are expected to be available. This means the TIP is not a “wish list” of projects but a realistic one. Projects that are not progressing might be removed from the TIP, and this makes the inclusion of projects in the TIP competitive.

Per the federal law, the TIP should cover a minimum of the next four years and follow the federal fiscal-year schedule. The usual practice is to cover the next five years and include a post-five year period, too. The TIP is updated every year in addition to adding amendments from time to time. The

approved TIP can be modified or amended in order to add new projects, remove projects, advance projects, and/or accommodate changes in cost, phase of work, or scope of a project.

Funding

The TIP is funded by a variety of sources, although the major source is the federal government. The federal transportation legislation authorizes the federal surface transportation programs for highways, safety, and transit. These programs are administered through the U.S. Department of Transportation’s Federal Highway Administration (FHWA) and Federal Transit Administration (FTA). The funds are provided through the Federal Highway Trust Fund (generated primarily from fuel tax).

These funds are apportioned among the states and metropolitan areas by formula. Most FHWA sources of funding are administered by the state departments of transportation (DOTs), while most transit funds are sent directly from the FTA to the transit operator. These funds are distributed as reimbursements for costs as they are incurred. Generally, 20 percent matching funds from the project sponsor are required by the federal law. Project sponsors can include states, counties, municipalities, private developers, toll authorities, and transit operators.

Development Process

The development of the TIP is a result of the transportation planning process and is the responsibility of the MPO. It is arrived at through a consensus-building process among state, regional, and local officials who are members of the MPO. This consensus-building process assures the federal and state governments that all interested parties have participated in the process and agree with the outcome.

As mentioned earlier, projects in the TIP are expected to realize a long-range vision. The municipal planners and engineers develop a list of projects based on their needs analyses and citizen complaints. If they think they need financial assistance, they bring the project to the MPO table for consideration.

MPOs solicit projects to be included in the TIP periodically. The MPO staff, with the assistance of experts from other regional and state agencies, as well as task forces and working groups, review and rank the projects based on various criteria agreed to by members of the MPO.

The projects may compete in a common pool or under different categories. Usually, the projects showing urgent need, higher benefit-cost ratios, and furthering the long-range vision (highest priorities of the region) get ranked highly. The MPO staff present the recommendations to the technical committee (planners and engineers from member municipalities and agencies) and the committee discusses and recommends the list (with any modifications agreed upon by the committee) to the MPO policy board (elected officials from member municipalities and representatives from participating agencies). The final recommendation is placed for public comment and any comments received within the stipulated time are incorporated into the TIP. This final TIP is then adopted for potential funding.

TIP and Air Quality

The Clean Air Act requires the U.S. Environmental Protection Agency (EPA) to establish the National Ambient Air Quality Standards (NAAQS) for various-criteria air pollutants. Areas where air quality monitoring shows a violation of the NAAQS are designated “nonattainment areas.”

By law, each nonattainment state is required to prepare a plan, known as the State Implementation Plan (SIP), that identifies how it will attain and/or maintain the NAAQS. The SIP is administered by the EPA through state environmental agencies.

In nonattainment states, TIPs must conform to the SIP. The MPOs and DOTs must demonstrate that the overall impact of the projects in a TIP will not have adverse impacts (that is, create new violations, increase the frequency or severity of existing violations, or delay attainment of the standards) in order to be approved for inclusion in the TIP.

Implementation

Once a project is in the TIP, the lead agency (county, municipality, state DOT, or transit agency) details the engineering aspects, design, right-of-way acquisition, and construction. The project will then be implemented according to its schedule.

Projects may be delayed because of a variety of reasons, including environmental issues and community concerns. These delays are identified and remedied as soon as possible. If required, appropriate amendments are made in the TIP to accommodate the cost or schedule changes. In the worst case,

a project might be removed from the TIP if there is no progress over a long time.

TIP and STIP

The TIP is different from the Statewide Transportation Improvement Program (STIP). The STIP is the state’s four-year transportation and capital improvements program. The STIP lists federally funded transportation projects that are located outside the MPO boundaries, in addition to incorporating the MPO TIP projects. The TIPs of MPOs are included in the STIP by reference without modification once approved by the MPO. The projects in the STIP include highway, bridge, public transit, bike, pedestrian, railroad, and other improvements. The STIP is prepared by the state DOTs.

Transportation Modeling and Planning Software

Transportation models, defined as a simplified representation of a system, focus on selected elements

considered important for its understanding and analysis. They attempt to replicate the behavior of a system using mathematical formulations based on certain theoretical statements and observations. Although they are simplified representations, models may be very complex and often require large amounts of data and computational resources.

However, since the advent of low-cost and high-capacity computing, the uses of transportation modeling in enabling forecasts, evaluating alternative plans and scenarios, identifying the relationship between land use and travel patterns, and improving the decision-making process have been largely facilitated. Since the mid-1950s, when transportation modeling was first developed, several models and planning software have emerged.

Modeling Approaches

The general structure associated with transportation modeling was developed in the 1960s and has remained mainly unchanged despite major technological advances in the last decades. The approach concerns a sequence of four sub-models: trip generation, trip distribution, mode choice, and traffic assignment over a network.

Because travel decisions are not actually taken in this kind of sequence, several contemporary approaches on transportation modeling consider the simultaneous processes of trip generation, trip distribution, and mode choice. Other recent approaches focus on the activities of travelers and the choices they entail, aiming at a clearer understanding of travel behavior.

Model Taxonomy

Transportation models are classified in various categories in order to determine their appropriate use in the planning process and to identify their properties and differences. Their classification can thus be based on various dimensions.

A deterministic model does not include any randomness. Thus, an event can either occur or not occur. Repeated applications of a deterministic model will produce the same results. However, if certain attributes or inputs of the model are subject to any randomness (or not known with certainty), the model is defined as stochastic. In such models, different random number sequences will produce different results, indicating a probability of certain outcomes.

A model is defined as time-based when time advances from one point in time to the next based on constant steps. A model is event based when time progresses based on the occurring events, thus skipping certain points in time.

Off-line models are mainly used for evaluating what-if scenarios or testing various alternatives, while online models open up the possibility of continuous data input. If these data are real-time data, then real-time models can be developed that progress according to the rate at which time actually advances.

Real-time models are mainly used for managing and controlling traffic at real-time level (for example, traffic signal controllers) and are often attached to a physical traffic control device. Because computational requirements are considerably lower than those of real-time models, off-line models can simulate the behavior of a system at a rate often faster than real time.

Analytical models deal with the prediction of the performance of a system based on the validation, calibration, and statistical analysis of field data. If the modeled system has a logical structure and is not governed by discontinuities, an analytical solution can be obtained.

When analytical models are not applicable, simulation models are used. Such models use mathematical and numerical techniques for creating an inventory of possible events and assessing their impact for one or more variables of the model. However, they require a rather significant amount of input data, which in turn need to be validated and calibrated before used.

Static and dynamic models are differentiated based on the temporal nature of traffic flow and whether this is captured by the model. Static models are widely used in strategic transportation planning and analysis. They consider that origin-destination (OD) matrices, describing travel demand, are fixed over time and do not change throughout the duration of the analysis period, are inputted only once, and thus imply a steady state of traffic loading.

In contrast, dynamic models can describe time-varying networks and demand interactions using a behaviorally sound approach, and they can capture the temporal nature of traffic phenomena, such as congestion. Such models also consider that OD matrices can vary over time and depict the behavior of a system in a more realistic way.

Most models capture changes in the OD matrices once for every hour (hourly step), while some allow changes in shorter time intervals (for example, five- to 15-minute steps).

Since the advent of intelligent transportation systems (ITS), and the need for modeling the provision of travel information and guidance according to real-time conditions, the development of models accounting for flow changes relevant to time has emerged vigorously.

Macro-, Micro- and Mesoscopic Models

The most frequently used method for classifying transportation models is based on the level at which traffic flow conditions are represented and the details a model takes into consideration. Macroscopic models deal with the representation of traffic flow in a fluid aggregated way. As such, they include a limited amount of detail, which accounts for their ability to execute quickly and in a computational resourceful way. Such models focus on large geographical areas and usually consist of a large number of components (for example, zones, nodes, links).

Microscopic models deal with the movement of individual vehicles in an examined network and their in-between interactions. Such models incorporate the logic and methods according to which vehicles move laterally (lane-changing theory) and longitudinally (car-following theory), and how they accelerate, decelerate and change lanes. Microscopic models include a significant amount of details and data and are thus more computationally demanding than macroscopic models. They focus on evaluating the performance of a selected facility rather than the whole system, and thus focus on small geographical areas.

Mesoscopic models are models characterized by both macro- and microscopic features. Such models consider the movement of clusters or platoons of vehicles and also model their interaction, but do not take into account lane changing or other vehicle behaviors.

Planning Software

There exists an important distinction between transportation planning models and transportation planning software packages. While models serve as analysis tools necessary for study, design, and evaluation of typically large-scale and complex

transportation systems, software packages are tools that implement transportation planning models. As such, they usually include several sub-models, represented by different mathematical formulations, depending on the nature of the model itself. The software packages that are presented here are broadly classified based on the included level of detail (macro-, micro- and mesoscopic) and the applications for which they are mostly used. Because application areas are not completely distinct, many software packages often fall under more than one category.

Macroscopic Software Packages

VISUM is a macroscopic model that allows the modeling of all types of private and public transport types in one single integrated model, as well as the management of geographic information system (GIS)-based data. The software includes several sub-models associated with the four-step modeling approach and is currently widely used for a series of applications, including the overall planning and analysis of networks, the prognosis of impacts of road tolls, and the design and analysis of public transport timetables.

TRANSCAD is a transportation planning software at a macroscopic level, initially developed as a GIS, which also combines transportation modeling capabilities in a single integrated platform. It can be used for all modes of transportation, at any scale or level of detail. It is widely used as a tool for building transportation information and decision support systems, and it fully integrates GIS with demand modeling and logistics functionality.

CUBE is a suite of transportation modeling that encompasses various sub-models for working at different levels of detail. CUBE Voyager works according to the traditional four-step modeling approach or with any model type that uses highway assignment. CUBE Dynasim is a microscopic simulation model developed for detailed analyses and studies of selected areas.

QRS II/GNE package is used for a variety of purposes, including regional transportation studies, site impact analysis, transit planning, and database analysis. The GNE refers to the General Network Editor, which provides the means to input and read network-based data (node and link characteristics). QRS II stands for Quick Response System II and runs the four-step planning process—trip generation,

trip distribution, mode split, traffic/transit assignment—for highway and transit forecasting.

TRANSYT (TRAFFIC Network Study Tool) is a deterministic simulation and optimization tool used for modeling traffic in signal-controlled areas. The model looks for a combination of signal timings that minimize overall vehicle delay and coordinate signal controllers in such a way that clusters of vehicles can pass without stopping.

NETFLO (NETwork traffic FLOW simulation model) simulates traffic conditions both at a stochastic, event-based level and at a deterministic time-based level. NETFLO and FREFLO, a macro freeway model, are now integrated in a single simulation system CORFLO.

FREQ is a deterministic simulation model for freeway corridors, ramp metering, and high occupancy vehicle (HOV) facilities analysis and evaluation. Its main weakness lies in the simplification of arterial alternatives and lack of full rerouting techniques.

KRONOS is a simulation model developed for freeways, which incorporates a continuum model for representing traffic flow while also modeling lane changing, merging, and spillback behaviors, which are not included in other macroscopic freeway software.

CORQ (CORridor Queuing) is a dynamic traffic assignment model developed for freeway corridors. Its main weakness lies in the expression of the travel-time relationship as a static step function of link flows. The time relationship is insensitive to changes in signal timings on parallel arterials. Because CORQ was perhaps the most detailed corridor-level model throughout the 1980s, parts of its modeling approach were modified and incorporated into the design of the area-level integrated network simulation models INTEGRATION.

Microscopic Software Packages

VISSIM is a microscopic, simulation-based model developed for analyzing various road categories and urban networks. The software can model all modes of transport because it adopts several methods and theories that describe each separate mode. Although links are used in the model for describing road segments, VISSIM does not follow a node structure. Within VISSIM, a signal state generator (SSG) is included. The SSG allows the evaluation of impacts of several signal operations found in

the real world (for example, adaptive control, fixed time, actuated).

TRANUS is an integrated land use and transport modeling package combining a state-of-the-art model of activities location and interaction, land use, and the real estate market with a comprehensive multimodal transport model. The combination of these two models produces the highest benefits, but the transport model may be used as a stand-alone component, especially for short-term projections.

AIMSUN is a tool that integrates in a single software application the three types of transport models: static traffic-assignment tools, a new mesoscopic simulator, and a microsimulator.

Quadstone Paramics is a traffic and pedestrian microsimulation software for planning, designing, and analyzing transportation network performance, allowing operational assessment for current and future-year traffic conditions.

SYNCHRO's software suite is a complete solution for modeling, optimizing, and visualizing traffic networks. Using Synchro Studio and Warrants, traffic professionals can easily analyze capacity and timing optimization, as well as simulate, check, and fine-tune traffic signal operations.

NETSIM (NETwork SIMulation) is a microscopic model for a wide range of complex, multimodal traffic networks. Initially released in the 1970s, it provides a high level of detail using an interval-scanning simulation approach for the movement of individual vehicles, according to the car-following theory.

TRANSMODELER is a versatile traffic simulation package applicable to a wide array of traffic planning and modeling tasks. It can simulate all kinds of road networks, from freeways to downtown areas, and can analyze wide-area multimodal networks in detail. TransModeler models the dynamic route choices of drivers based upon historical or simulated time-dependent travel times, and also models trips based on origin-destination trip tables or turning movement volumes at intersections.

CARSIM (CAR-following SIMulation) models the behavior of individual vehicles on freeways according to car-following theory.

FREESIM is a stochastic simulation model based on a set of algorithms that simulate vehicle lane-changing and car-following behavior.

SCOT (Simulation of CORridor Traffic) is one of the first models for integrated networks. The software consists of two models, UTCS-1 (dynamic

traffic assignment at mesoscopic level) and DAFT (microscopic). The basic element of the model is its ability to integrate features from the two sub-models.

CORSIM is a microscopic simulation model designed for the analysis of urban networks and freeways. The model consists of two sub-models, namely FRESIM and NETSIM. A traffic assignment model is integrated in CORSIM for obtaining paths for given OD matrices.

INTEGRATION is a microscopic model of integrated freeways and urban networks, where individual vehicles' information (origin and destination) are input to the model. However, the routing of vehicles and their respective travel times are derived within the simulation. INTEGRATION is one of the first models to consider the interaction of ITS in vehicle guidance and routing.

Mesoscopic Software Packages

AIMSUN integrates in a single software application three types of transport models—traffic assignment models, a mesoscopic simulator, and a microsimulator. The microscopic model is developed based on car-following, lane-changing, and gap-acceptance algorithms. However, the new mesoscopic simulator in AIMSUN 6 provides an additional option to practitioners to model dynamic aspects of very large networks and removes most of the calibration burden when compared to a micro-simulator.

EMME is a transportation planning software package able to conduct complete travel demand modeling for urban, regional, and national transportation forecasting. Emme also includes a public transport model consisting of a combination of several analytical computer programs.

DYNUST (DYNAMIC Urban Systems for Transportation) is a simulation-based dynamic traffic assignment tool for regional operational planning analysis. Within DYNUST, the traffic assignment process includes the interaction of the simulation model and the time-dependent shortest-path module. DYNUST is based on an Anisotropic Mesoscopic Simulation (AMS) model deriving from previous models adopting a vehicle-based mesoscopic traffic simulation approach.

DYNASMART (DYNAMIC Network Assignment-Simulation Model for Advanced Roadway Telematics-Planning version) is a mesoscopic simulation model that includes demand-forecasting procedures for planning functions, as well as traffic

simulation models with dynamic traffic assignment and other operational applications.

CONTRAM (CONTinuous TRAffic Assignment Model) is a traffic assignment software dealing with traffic in urban networks. This model considers the movement of platoons of vehicles as single entities. The traffic assignment problem within CONTRAM is based on Wardrop's first principle and is solved through iterations in which platoons of vehicles are removed and reassigned to the network.

SATURN (Simulation and Assignment of Traffic in Urban Road Networks) includes a traffic simulation and assignment model for the analysis of various road-investment schemes over large networks. It also includes a separate function for simulating traffic flows at individual junctions.

Software Selection

Because the power of personal computers and the search for traffic management solutions to transport problems is increasing, traffic modeling has become a widely used tool for facilitating transportation planning and traffic engineering applications that are more and more important in traffic engineering.

Currently, there are many traffic simulation packages that tend to satisfy traffic engineering requirements. These simulation models can evaluate alternative scenarios, test new designs, or conduct safety analysis through the re-creation of traffic accidents. The selection of the appropriate simulation model requires the thorough and concrete consideration of many distinct parameters, such as the flexibility of the model, the ease of data collection, validation, calibration and coding, cost, training requirements, user friendliness of the software, and accuracy of the estimation of measures of performance, as well as expandability and the ability of the model to interact with other software. The importance of each dimension will depend on the nature of the activity, its objective, resources available, and user preferences. In fact, the software selection is fundamental to the success of an undertaken project, and this choice is usually a trade-off between the accuracy and the precision of the model and the development costs, data needs, and time required for execution.

Transportation Plan Implementation, Monitoring, and Evaluation

Transportation plan implementation, monitoring, and evaluation refers to an extensive process undertaken at the local level that involves gathering a wide range of input directed at specific problems in the region's transportation system, most often urban areas with populations over 50,000. Determining where to deploy federal monies targeted for surface transportation planning is central.

Establishing a clear protocol for maintaining transportation systems has three interrelated functions: (1) to set priorities and to define specific goals (as well as workable alternatives) to address those problems based on massive amounts of data gathered and analyzed by state, county, and local transportation planners as well by federal agencies and local transit authorities; (2) to determine how to allocate available federal monies to sponsor the projects and, in turn, devise practical schedules for implementation, and (3) to set standards to evaluate

the projects, to monitor the progress on approved programs, and to measure their effectiveness as a way to guarantee the region's continued mobility.

Transportation planning, because of its largely localized concerns, dispenses with the visionary and the idealistic to deal with immediate problems in a meaningful and organized way and to set clear and specific goals and take into account costs and funding.

Evolution in Transportation Planning

Transportation plan implementation has evolved into significantly more than a simple urban transportation wish list, a kind of to-do list of wide-scope projects that involve either highway development or rehabilitation or transit policy and improvement. Transportation planning now assumes the voice of a wide community interested in linking transportation system performance to long-term strategies for developing not only efficient and reliable transit systems but also to implement those systems as part of a much more comprehensive statement of the relationship between a community and its environment.

Transportation plan implementation is a way to shape not just the needs of a mobile society, a way to move both people and goods efficiently and safely about and around a metropolitan area, but to give that area a vision of its relationship to the land itself, how it will use and conserve land and resources, support growth, shape economic opportunity, and provide a strategy for the future. It is shaped by a meaningful collaboration of diverse perspectives from both the public and private sectors in order to draw up a plan for financing transportation system improvement, ways to maintain and evaluate that system, and make it ultimately part of real economic, social, cultural, and political community growth.

In the decades immediately after World War II, as automobile usage dominated American transportation planning, the process of transportation plan implementation was dominated by traffic engineers and civil engineers. They addressed concerns for maintaining urban and rural roadway capacities, as automobile mobility was seen as crucial to both regional and national economic viability to accommodate the new needs of a suburban workscape. For more than a generation, transportation planning used complicated mathematical

formulas to determine traffic patterns and their sustainability.

Planning was therefore dominated by concerns over destination analysis, congestion reduction, transportation mode preference, route selection, and trip distribution (the number of trips going from one destination to another). The assumption was simple: the future belonged to the automobile and to strategies that provided ways to move people efficiently, safely, and in the largest possible capacities.

By targeting specific traffic problems and extrapolating predictions of future problems, transportation planners worked to create automobile-friendly metropolitan areas. The urban landscape for decades was essentially redesigned with the automobile in mind, with strategies to maintain and minimize congestion, contain and direct volume traffic, and ensure the safety of drivers, all geared to increase mobility and system capacity. In turn, transportation plans initiated a sharp spike in construction—highways, streets, county roads—as the key to transportation efficiency. Evaluation was hardly a priority—spurred by vested interests in the automobile industry, hundreds of miles of highways were built, and there was evident need for more. It was, in retrospect, a very limited perception.

Beginning in the early 1980s, the single-minded agenda was found deficient as concerns emerged over the relationship between urban transportation systems and the environment that sustains it. With the passage in 1977 of the Clean Air Act Amendments, air quality and transportation systems were linked and cities began to examine both stationary and mobile sources of air pollution to set realistic reduction targets with clear planning horizons, usually three to six years. As hard data began to suggest the surface transportation system was having long-term effects on air, water, and noise pollution, transportation plan implementation began to consider more than simply increasing the efficiency and capacity of cars.

Urban planners recognized that transportation planning needed a broader, more encompassing vision that would take into account social, economic, and environmental concerns, and that a variety of other transportation system alternatives including buses, railways, subways, and even bicycles and pedestrian transit needed to be incorporated.

The key was integration—strategies to integrate transportation systems with the environment, current transportation needs with future needs, and ways to integrate transportation systems with community needs broader than simply efficient traffic flow. In turn, transportation planning has become multidisciplinary, including not merely politicians, lobbyists, and engineers but also environmentalists, economists, educators, medical professionals, entrepreneurs, utilities experts, computer software engineers, and climatologists.

Although the goal is still an improved transportation system, it now encompasses emission standards, water quality, enhancing economic opportunities, improving the quality of life in neighborhoods, and encouraging responsible mobility through public education initiatives (a concept that itself includes a wide range of options including using more fuel-efficient cars). Among the strategies under consideration are conserving the number of trips; sharing rides along well-used transport corridors and main arteries leading into the city; constructing priority lanes for high-occupancy vehicles that provide higher speed limits and avoid traffic jams in other lanes; prioritizing transportation options for buses and restructuring bus routes to maximize rider appeal; reducing the speed of vehicles, particularly in residential streets; providing perimeter public parking for commuters willing to use public transportation into the city; encouraging the construction of bike lanes and even redesigning urban streets to prohibit vehicular traffic altogether; promoting city transit systems by expanded schedules, improved stop facilities, and timely service; and encouraging businesses to experiment with flextime schedules to minimize traffic during peak hours.

In short, transportation planning now emphasizes complex and multilayered system management rather than simple system expansion.

Transportation Implementation: Goals and Process

Because transportation planners now recognize how broad and how deep is the impact of a city's transportation system—influencing environmental well-being, cultural and social development, financial and economic viability, neighborhood rehabilitation, tourism, even the aesthetic and visual impact of the cityscape itself—implementation has begun to consider strategies to use transportation

systems to improve the livability of the communities they service. But that can be a difficult goal, easier to state in visionary (and quixotic) rhetoric than to actually achieve. However, transportation plan implementation aims to do just that.

The process works through a series of linked steps. The process begins with a centralized metropolitan planning organization (MPO), a proactive think tank/public policy board. Since the mid-1970s, urban centers of more than 50,000 are required to have a commission whose responsibility is to provide an effective and public setting to make public transportation policy—a board made up of local and state transportation agency representatives as well as transit system operators and whose meetings and operations are matters of public record.

The MPO monitors existing transportation systems and provides a forum for the exchange of information about concerns and/or project proposals for the metropolitan area. In that capacity, the MPO looks at a variety of issues involving transportation systems and environmental health, a process that involves the participation of the public, as spending federal monies is the core responsibility. Although the process is necessarily flexible and addresses concerns endemic to the metropolitan areas served, generally the MPOs work toward seven broad goals:

- In cooperation with demographers, drawing up comprehensive probability statistics on population and business growth
- In cooperation with environmental engineers and a host of technical support staff, assessing and projecting land use and resource availability as it relates to potential transportation system development
- Identifying current and potentially long-term problems and needs that are directly related to the efficiency and capacity operation of surface transportation systems with input from business interests, public advocacy and community interest groups, environmental organizations, freight operators, airport authorities, private transportation providers (such as taxicab services), port authorities, rail executives, public transit representatives, and (especially) the general public who depend on transportation systems
- Developing a specific list of both long-term and short-range initiatives that would provide both the essential capital improvement necessary to alleviate transportation problems or at least minimize their impact and preserve the area's environmental viability
- Providing specific and concrete information on the impact of potential/proposed projects the problems and needs originally identified
- In cooperation with federal agencies and individual state department of transportation and both county and city financial networks, developing real-time cost-effective strategies for financing the project
- Providing a specific agenda for monitoring projects and evaluating their short- and long-term impact as a way to guarantee a timely and meaningful process\

Transportation planning implementation involves specific documents that state and regional transportation planning agencies prepare and make available to the public. These documents provide the ongoing narrative for transportation planning, monitoring, and evaluation, and in turn provide a public record of state and regional planning efforts to develop both an efficient and cost-effective surface transportation system. These documents attempt to provide a coordinated general pool of information about projects under consideration and projects under way:

The Unified Planning Work Program, commissioned every year, is a public archive that keeps a record of all ongoing regional transportation studies, often with specific attention to clean air quality standards, the emissions budget, and those projects already vetted and now in the data-gathering stage as a way to provide a clear vision of the general direction of long-range assessment transportation planning.

The Metropolitan Long-Range Regional Transportation Plans, commissioned every five years, covers at least a 20-year period. This document, usually multivolume, provides a record of those transportation projects currently in process and/or approved along with supporting materials, technical, environmental, and economic, that define both the problems and the goals of the projects.

The Transportation Improvement Plan, commissioned every four years, is an archive that provides a record of the short-term projects actually undertaken from the Regional Transportation Plan and provides a record of the allocation of federal funds.

The State Planning and Research Program is a summary of the research activities and project tasks and an identification of funding sources and the agency commissioning the research.

The Statewide Long-Range Transportation Plan, the plan with the broadest project horizon (up to 20 years), records the long-term projects that involve not only additional construction projects but also ways to maintain and preserve long-term use of existing surface transportation routes. It includes car-centric systems as well as transit programs and nonmotorized systems as a way to direct and coordinate long-term transportation system viability.

Although critics of the cumbersome bureaucracy involved in transportation planning implementation are quick to point out the redundancies in these mandated records and the enormous amount of paperwork and time consumed in preparing them (not to mention the public money required to maintain the superstructure of committees necessary to generate the paperwork), advocates of the system point to the research data and the public record as a way to maintain transparency, and the frequency of documentation as a way to maintain projects' focus and to ensure attention to critical issues in both surface transportation accessibility and efficiency, as well to achieve crucial environmental standards.

At the core of all transportation planning implementation, of course, is not the public archiving of research data or project recommendations but rather the dispensation of federal funding as a way to realize short-term projects with long-term benefits. The goal of all transportation plans is the actual implementation. Although projects are funded by and through an often bewildering entanglement of resource pools (funding for transportation projects can come from state monies, special allotments at the local level, public and private toll systems for users, and local general assessment funds, such as property taxes or sales taxes), the primary

component of transportation implementation is federal funding made available through the federal Highway Trust Fund.

Those funds are given to the state Department of Transportation that, in turn, oversees the reimbursement of local projects—monies from the federal government are not up front. Traditionally, funding from the federal government was strictly separated between highway projects and transit system projects; over the last generation, however, recognizing the increasingly interdependent nature of metropolitan transportation systems and to provide local transportation authorities the chance to respond to conditions and emergencies as needed, the federal government has initiated so-called flexible funding in which local MPOs can actually move the available federal funds freely between transit projects and highway projects according to needs assessments, emergency response conditions, and priority projects.

Issues in Transportation Plan Implementation, Monitoring, and Evaluation

To give some idea of the breadth of issues transportation implementation plans consider is to realize that, although first consideration is given to relatively localized needs and arterial transportation efficiency for the immediate service area, transportation implementation across the country considers several shared issues:

Air quality: The tie between surface transportation systems as well as stationary sources and the quantity of air pollutants ensures that the transportation system emissions rates do not exceed the area's federally mandated emissions budget. Areas that fail to meet that standard, termed non-attainment zones, require priority attention, as federal funding provisions hinge on meeting clean air standards.

Congestion management: MPOs, recognizing the need for efficient operations and open arterial flow in transportation systems, identify regularly congested areas (and those specially designated intersections around major sporting facilities, large-scale shopping venues, business centers, concert/entertainment sites, and university areas prone to regular traffic spikes) and propose alternative roadways, lane redistribution or construction, high occupancy

vehicle (HOV) programs, ramp redesign, the installation or removal of traffic lights, emergency vehicle deployment strategies, and weather contingency operations.

Freight movement: Although enormous public attention is paid to the challenge of moving private vehicular traffic through urban areas, on any given day transportation board data estimates that such private vehicular traffic accounts for less than 40 percent of the arterial flow in a metropolitan transportation system.

Because so much of the local and regional economy depends on the access to and use of highway systems (and streets) by trucks ranging in size and weight loads, lobbyists for the trucking industry regularly petition MPOs on a range of issues involving truck lanes, efficient operations of weigh stations, fuel and truck plaza availability, speed limit ranges, ramp layout and safety, congestion management, traffic light installations and control, as well as emergency assistance programs, all of which influence transportation plan implementation.

Safety and security: For decades, urban management planners have been concerned over emergency vehicle availability, usage, and routing as well as locating and addressing potentially hazardous interchanges or road systems and providing effective speed limits and mandating safety-first driving habits (including wearing seat belts but also restricting driver distractions such as handheld cell phone use and texting).

Broad concerns in transportation planning include not only the safe transport of potentially hazardous materials through a metropolitan transportation system but also concerns raised in the last decade over the targeting of public transit for terrorist attacks, the use of public highway systems for transportation of such weaponry, and the use of public transportation systems for first responders in the event of a widespread emergency.

Technology application: Over the last generation, computer software engineers have become key elements in transportation plan implementation and monitoring, introducing cutting-edge applications able to provide immediate real-time data on traffic flow and to provide drivers with accurate

information on problem areas; maintain better data on air quality; monitor weather conditions; improve efficiency in traffic control by law enforcement; upgrade trucking and freight monitoring; and improve operations at both ports and airports. Because technology is the new frontier in transportation plan implementation, urban planners recognize the potential in computer assistance to better maintain traffic patterns, monitor land and air usage, catalog fuel supplies, route emergency response teams, and enhance safety operations in all phases of urban transportation systems.

Environmental justice: The responsibility of the MPO planning process is to ensure that the maintenance and improvement of transportation services are fairly distributed among a metropolitan area's diverse socioeconomic communities without regard to economic status, ethnic makeup, or gender and age; to ensure that traffic difficulties and health concerns do not disproportionately impact lower-income neighborhoods; and to guarantee all segments of a city's population are given fair access to the planning process and input in the approval—or rejection—of projects.

Although the process of transportation plan implementation and the subsequent monitoring of its effectiveness and the evaluation of its sustainable impact can seem bewildering and overly bureaucratic, the urban planning system provides a clear, collaborative, and transparent process to address transportation concerns and reasonable and timely protocol for real-time improvement.

Transportation Planning

“Transportation planning” is a broad term that has many meanings. To some, it might mean fixing the potholes in the neighborhood streets. To others, it might mean trying to solve the massive congestion characteristic of most urban areas. To others still, the term might conjure up futuristic transportation vessels as were depicted in the movie *Blade Runner*, or even in the 1960s cartoon *The Jetsons*. In truth, the multidisciplinary field of transportation planning covers all of these areas and more.

Transportation planning is the functional area within transportation engineering that deals with the relationship of land use to travel patterns and travel demands; and the planning, evaluation, and programming of transportation facilities, including roadways, transit, terminals, parking, pedestrian facilities, bikeways, and goods movement.

Transportation planning plays a fundamental role in the state’s, region’s, or community’s vision for its future. It includes a comprehensive consideration of possible strategies; an evaluation process that encompasses diverse viewpoints; the collaborative participation of relevant transportation-related agencies and organizations; and open, timely, and meaningful public involvement.

Because transportation issues are frequently cross-jurisdictional, covering multiple cities, towns, counties, states, and sometimes even countries, most transportation planning is spearheaded by a regional planning organization, also known as a metropolitan planning organization (MPO). However, because MPOs are only mandated in areas with a population of 50,000 or more, in rural areas of the country, most planning is undertaken by state departments of transportation (DOTs).

Transportation planning is not only cross-jurisdictional; it is also cross-disciplinary. While there

are many professionals who work solely as transportation planners, transportation planning is a cross-disciplinary field, performed by a multitude of professionals, including not only planners but also engineers, landscape architects, environmental scientists, and economists, to name just a few.

Evolution of U.S. Transportation Planning

Urban transportation planning in the United States has generally always been conducted by state and local agencies. This is appropriate because most highway and transit facilities and services are owned and operated largely by the states and local agencies. The role of the federal government has traditionally been to set national policy, provide financial aid, supply technical assistance and training, and conduct research.

Over the years, the federal government has attached conditions to the financial assistance it provides. From a planning perspective, the most important has been the requirement that transportation projects in urbanized areas of 50,000 or more population be based on an urban transportation planning process. This requirement was first incorporated into the Federal-Aid Highway Act of 1962.

The Federal-Aid Highway Act of 1962 was the first piece of federal legislation to mandate urban transportation planning as a condition for receiving federal funds in urbanized areas. It asserted that federal concern in urban transportation was to be integrated with land development and provided a major stimulus to urban transportation planning.

Two features of the act were particularly significant with respect to the organizational arrangements for carrying out the planning process. First, it called for a planning process in urban areas rather than cities, which moved the scale to the metropolitan or regional level. Second, it called for the process to be carried on cooperatively by the states and local communities.

Because qualified planning agencies to take on such a transportation planning process were lacking in many urban areas, the Bureau of Public Roads (BPR) required the creation of planning agencies or organizational arrangements that would be capable of carrying out the required planning process. The growing momentum of the highway program, coupled with the cooperative financing of the planning process by the Housing and Home Finance Administration (HHFA) and the BPR, helped lead to the

formation of numerous regional planning agencies around the country.

U.S. Department of Transportation

Other legislation that helped grow the transportation planning industry followed. In 1966, the U.S. Department of Transportation (USDOT) was established. Its mission was to coordinate transportation programs and to facilitate the development and improvement of coordinated transportation services utilizing private enterprise to the maximum extent feasible. The Federal Aid Highway Act of 1968 established the Traffic Operations Program to Improve Capacity and Safety (TOPICS). The program was designed to reduce traffic congestion and facilitate the flow of traffic in urban areas.

The Federal Aid Highway Act of 1970 established the federal-aid urban highway system. The system in each urban area was to be designed to serve major centers of activity and to serve local goals and objectives. Routes on the system were to be selected by local officials and state departments cooperatively. This provision significantly increased the influence of local jurisdictions in urban highway decisions.

The Federal Aid Highway Act of 1973 contained two provisions that increased flexibility in the use of highway funds for urban mass transportation. First, federal aid urban system funds were to be used for capital expenditures on urban mass transportation projects. Second, funds from the Highway Trust Fund (HTF) could be diverted to mass transportation projects.

Therefore, the 1973 Federal Aid Highway Act took a significant step toward integrating and balancing the country's highway and mass transportation programs. It also increased the role of local officials in the selection of urban highway projects and broadened the scope of transportation planning by MPOs, which were to be designated by the states to perform this planning function.

1980s and 1990s

With five titles and 149 sections, the Surface Transportation and Uniform Relocation Assistance Act of 1987 (STURAA) was passed by Congress on April 2, 1987. The STURAA authorized \$87.6 billion for the five-year period from fiscal year 1987 to fiscal year 1991 for the federal aid highway, safety,

and mass transportations programs. It also updated the rules for compensating persons and businesses displaced by federal development and extended the HTF through June 30, 1994.

The 1980s brought a new challenge to urban transportation planning—the decentralization of authority and responsibility. The national mood had shifted, and centralized approaches were no longer considered to be the appropriate means for dealing with national problems. The federal government started to reduce its involvement, which left the states and local governments with more flexibility to fashion their planning procedures and institutions to their own local problems and needs. More time and effort could be used to produce information for local decisions rather than to meet federal requirements. The federal statutes remained in force, but additional federal guidance or elaboration was reduced and eliminated.

On the other hand, however, planning had to be more responsive to the needs of local decision makers and citizens, and to adjust to the realities of long-term budget constraints in many urban areas. The urban transportation planning processes had been attuned to federal requirements and had to realign procedures and institutional arrangements to address local issues and needs.

Many of the issues that were debated in the 1970s were revisited in the 1990s. One issue was the appropriate balance between long-range and short-term planning. A second was the level of effort devoted to system expansion, infrastructure rehabilitation, system management, and possibly even system retrenchment (for example, removal of certain facilities or routes) to match declining population, travel demand, and financial resources.

The issues of changing institutional arrangements and locus of decision making were being raised in a number of urban areas. Many urban areas are attempting to use transportation to foster economic development while still providing mobility. The use of innovative financing techniques such as special improvement districts (SIDs), business improvement districts (BIDs), and public-private partnerships (PPPs) have increased to offset shortfalls in public-sector funds.

Environmental quality, transportation for special groups (that is, the poor, the disabled, and the elderly), and sustainability began to take on greater significance across the spectrum of urban

Park-and-ride stations like this one in Denver, Colorado, offer people the option of leaving their vehicles close to home and transferring to a bus, rail system, or carpool for the remainder of their journey. The location of these park-and-ride stations is critical to their success. They must be conveniently located in the suburbs of metropolitan areas or on the outer edges of large cities in order to attract commuters.

areas and broadened the transportation planning field considerably.

The Transportation Planning Process

Transportation planning is a cooperative, collaborative, and continuous process designed to foster involvement by all users of the system, such as the business community, community groups, environmental organizations, the traveling public, freight operators, and the general public. In the United States, most transportation planning is led by the MPO, in consultation with the federal and state DOTs, transit operators, and the federal and state environmental agencies.

Transportation planning includes a number of steps. The first is to establish a regional vision and goals. Many communities have extensive visioning exercises, which usually involve extensive public outreach. The visioning process is used to lay out goals, which are more specific statements identifying what a community wants to achieve. While goals

can vary from plan to plan or region to region, they are usually general. Examples of goals are “Improve Transportation Safety” or “Rebuild and Maintain the Region’s Transportation Infrastructure.”

The next step, development of alternate improvement strategies, consists of identifying current and projected future transportation problems and needs and analyzing, through detailed planning studies, various transportation improvement strategies to address those needs. The strategies can be operational, such as traffic signal synchronization; capital improvements, such as widening a roadway; or system management, as in incentivizing the implementation of carpooling and vanpooling programs.

In most cases, the transportation system’s needs far outweigh the financial resources available to implement these strategies, and so transportation planners must next evaluate and prioritize strategies. They do this utilizing a wide range of tools, including cost-benefit analysis, and specialized programs known as asset management systems, which

help decision makers to identify and prioritize capital expenditures when resources (funding and personnel) are limited.

In addition to evaluating the financial resources required to implement strategies and projects, planners and engineers use specialized tools and models to determine the impacts of various strategies on system attributes such as traffic congestion, air quality, and traffic safety. All of these tools aid planners in determining which projects and strategies should move forward.

The hallmark of any transportation planning process is the long-range (sometimes known as regional or metropolitan) transportation plan (LRP). This plan covers a horizon of at least 20 years and identifies specific programs, strategies, and projects that will help a community or a region achieve its transportation goals.

Under federal law, all transportation projects receiving federal funding must come from a long-range plan. In addition to specific projects and strategies, long-range plans assess future travel demand via future population and employment forecasts, as well as identify major growth corridors that are likely to need major transportation improvements.

In some plans, land uses are projected as well. Under the Federal Planning Rule, all long-range plans must also include a financial plan to show that there will be sufficient revenues to cover the costs of implementing all these proposed projects. Many plans also include “aspirational” projects, which function more as a “wish list” of projects that are desired but for which there is no identified funding source.

The development of a transportation improvement program is the step of the transportation planning process where funds actually are programmed and committed to a project. The programmed funding and detailed list of projects are published in a Transportation Improvement Program (TIP), usually covering four years but updated more frequently. As with the long-range plan described above, for any project to receive federal funds, it must be in the TIP.

Transportation planning also involves project development, which is the process that takes a project from concept through construction. Project development is initiated in response to an identified need in the transportation system. As described above, the need might include one

or more of the following: a congestion problem, a safety concern, pavement or bridge deterioration, an environmental enhancement, or even an economic improvement opportunity. It covers a range of activities, beginning with identification of a need to a finished set of contract plans, completion of all environmental documents required, and construction.

An integral part of the transportation planning process is implementation of strategies and projects as programmed in the TIP and long-range plan. In many areas, transportation planners are removed from the implementation process. However, this is changing as fiscal constraints and an increased emphasis on expediting project delivery are forcing transportation planners and system operators to integrate their roles and responsibilities. This is especially noticeable in the congestion management process, in which planners may initially identify congested locations and problem areas and suggest potential strategies to mitigate the problem, but still need the expertise of operations officials to assess the feasibility of implementing these strategies.

Once projects are implemented, a transportation planner’s job is not over. A major part of the transportation planning process is monitoring the recently implemented strategies and projects to see how the system is performing and whether the goals outlined in the long-range plan are being met. Indeed, the recent federal legislation known as MAP-21 (Moving Ahead for Progress in the 21st Century), has put increased emphasis on measuring system performance and on comparing performance metrics against specific targets to which state DOTs will have to adhere if they want to continue receiving federal transportation funds.

Components of Transportation Planning

Even within the transportation planning field, the following different components of transportation planning exist.

- *Traffic operations:* The analysis, review, and application of traffic data systems to the operation of transportation facilities
- *Traffic design:* The determination of travel patterns and parking characteristics of transportation users in the planning and design of transportation facilities

- *Traffic research:* The conduct of theoretical and applied research to understand and develop new applications of technology that improve mobility, enhance the environment, and conserve energy resources

Transportation Authorization Legislation

Notwithstanding the legislation described earlier that helped give rise to the transportation planning industry, there has been a series of transportation reauthorizations in the past several years that have greatly enhanced the role of transportation planners in authorizing and allocating federal funds for transportation improvement projects. They are summarized in Table 1.

The current transportation authorization bill, MAP-21, funds transportation from fiscal year 2012 to fiscal year 2014 at \$105 billion each year. As mentioned above, there is a much greater emphasis on performance measures and targets, to which state DOTs and, by extension MPOs, must adhere.

This is the first step toward creating a true performance-based budgeting process for prioritizing how the United States invests in transportation. This approach is intended to provide taxpayers with the best return on their investment, while also improving livability and promoting global competitiveness.

The law also creates new regional transportation planning organizations, which allow for greater involvement of nonmetropolitan areas in planning. Further, the bill consolidates a lot of existing programs and delegates more authority to the states in making transportation planning decisions.

Challenges

Not surprisingly, the greatest challenge facing transportation planners is highly constrained financial resources, which are hindering the ability

of planners and engineers to make the needed improvements to America's transportation system. America's roads received a grade of "D" in the American Society of Civil Engineers' (ASCE) recent report card, which determined the need for \$170 billion in annual investment, almost 90 percent more than the current actual roadway investment of \$91 billion.

Further, transportation planning must be conducted in a highly politicized environment, which makes getting projects done very difficult. More and more, politicians focus on short-term measures that will help their election prospects rather than long-term investments, such as infrastructure.

Nothing is more politically unpalatable than raising taxes, probably the most common method for raising revenue for transportation projects. There is a large difference between what transportation professionals think should be spent and what Congress and state and local governments are willing to spend. Because much transportation planning is done on the regional level, and MPOs represent a multitude of city and county governments, it is difficult to attain consensus on major projects, especially in this era of fiscal constraint.

Many areas in the United States operate under "home rule," meaning that all power to regulate land use and zoning lies within each municipality. Because transportation planning, predominantly governed at the regional level, is intertwined with land use, which is governed at the local level, it is difficult for large, multi-jurisdictional projects, which often require changes in land use, to get done.

The Future of Transportation Planning

The level of detail and complexity of planning procedures is being reassessed. Smaller urban areas are opting for a simpler planning process that is

Table 1 Federal transportation reauthorizations, 1991 to 2012

Year Signed Into Law	Title of Bill
1991	Intermodal Surface Transportation Efficiency Act (ISTEA)
1998	Transportation Equity Act for the 21st Century (TEA-21)
2005	Safe, Accountable, Flexible, Efficient Transportation Equity Act: A Legacy for Users (SAFETEA-LU)
2012	Moving Ahead for Progress in the 21st Century (MAP-21)

commensurate with their fewer problems and less complex planning context. The larger areas have many more problems to address, options to evaluate, and organizational arrangements and procedures to use.

Greater emphasis in transportation planning is being placed on both the corridor- and site-level scale of planning, as opposed to the regional scale. As discussed above, there is growing awareness on the part of all planning practitioners that land use planning has to be integrated with transportation planning for it to be effective. Given the severely limited financial resources experienced by all levels of government, most of the future planning, at least in the near term, will be on system preservation and maintenance rather than new construction. A major contributing factor to the lack of funding is the diminishing value of the federal gas tax, which is the main source of revenue for the HTE, the chief source of funding for highway projects.

At 18.4 cents a gallon, the gas tax has not been raised since 1993. Meanwhile, the cost of highway construction and repair has increased 55 percent over the past 20 years. That means drivers today are chipping in the same \$3 in federal taxes per tank of gas that they paid in 1993, even as the construction projects being funded with that \$3 have become much more expensive. This has led to a deep shortfall in the HTE.

The Congressional Budget Office (CBO) projects that by 2015, the HTE will have insufficient revenues to meet its obligations, resulting in steadily accumulating shortfalls. According to a CBO report issued in 2013, federal lawmakers would have to cut transportation spending by more than 92 percent or increase the gas tax by more than 50 percent to bring revenue in line with transportation spending. Indexing the gas tax to inflation would put transportation revenue on a much more sustainable path. Had it been indexed to inflation, the gas tax would be about 29 cents today.

Some people have proposed a tax on the number of miles driven, known as a vehicle-miles traveled (VMT) tax, as a way to increase highway revenue. Vehicles would be charged a per mile fee, with heavier vehicles that cause more wear and tear on the road being assessed a slightly higher fee. Possible methods of enforcement could be the electronic toll collection, already common on many freeways and expressways, and for local roads, an

odometer reading associated with annual vehicle registration renewal.

Even though Congress passed a transportation reauthorization bill in the summer of 2012 with MAP-21, it spans only two years, hardly enough time for states and regions to make long-term capital spending plans, particularly when transportation projects can span multiple years. Further, with federal assistance declining and the trend expected to continue at least in the near term, most of the burden for funding infrastructure will fall to state and local government entities, which are as—if not more—strapped than the federal government. It is likely that some important construction will be deferred.

With rising costs and the uncertainty about how future projects will be funded, policy makers are looking for effective alternatives for both funding new and maintaining current, transportation infrastructure. In many areas around the country, businesses have joined together to create public-private partnerships (PPPs), contractual agreements formed between a public agency and a private-sector entity that allow for greater private-sector participation in the delivery of transportation projects.

PPP projects often are undertaken to supplement conventional procurement practices as a way to achieve cost and time efficiencies and expand funding sources, thereby reducing demands on constrained public budgets. While practices among different PPPs may vary, members of the PPP propose to pool financial and construction-related resources to build and finance projects. In transportation projects, PPPs have been used across the country because of their effectiveness and ability to reduce costs and construction times.

Transportation Planning and Politics

Transportation planning refers to the processes through which a vast array of measures and activities are undertaken that combine to manage the transportation network. Transportation politics refers to the decision making and dialogue that occurs to determine which transport infrastructure gets built or refurbished, which new investments

get prioritized, and how funding for transportation is allocated and spent. These processes differ in contexts across the world, and while there may be similar norms across cities, regions and countries in the world, there is no one overarching standard.

By their very nature, then, transportation planning and politics are often complex processes that are difficult to understand because of the number of stakeholders involved and the relationships between them. Delivery of transport projects is often conducted by third parties and public-private partnerships are increasingly popular. On the whole, responsibility for transportation planning is separated by mode and across and between levels of government.

Certain interactions that occur can be described as hierarchical, but there have been calls for more networked and participatory planning, development, and delivery of transportation because of increased awareness of the need to consider social and environmental factors of transport, as well as only economic considerations as has traditionally been the case. There is a large bureaucracy surrounding the planning and politics of transportation, and, as such, it is difficult to offer a complete picture of the processes that occur as a whole. Much has been written on road and city-based planning and will be the primary focus here.

Traditional Transportation Planning

While there are no common norms through which transportation planning occurs across the world, with local and regional variations commonplace, certain generalizations can be made about the similarities that exist in the way transportation planning occurred in most Western economies for the greater part of the 20th century. Road infrastructure is planned for, managed, and maintained by a host of parties.

Land use policy and local roads have generally been the purview of local authorities; regional/state roads are managed by regional or state authorities; and highways, freeways, interstates, and motorways are generally handled by a national/federal government. With regard to public transport, bus and light rail transit are typically run through a mixture of local, regional, and national companies—often in partnership with one another, which makes the management and maintenance of routes, fleets, and service a complex system to manage.

Freight transport and passenger transport have different needs and often find themselves in competition for resources, including space on the network. Transportation planning often considers the needs of passenger or freight transport in isolation, which can perpetuate these incompatibilities. With regard to rail, in certain countries, passenger and freight rail is nationalized in others, such as the United Kingdom, it has become privatized, leading to differing types of rolling stock and introducing competition for routes and a fragmentation in terms of services and providers.

Planning for walking and cycling infrastructure is generally managed by local authorities but has not been considered historically in major road projects, especially in the United States. Therefore, the provision of nonmotorized transport has until recent years been limited, and remains so to a large extent. Many transportation departments would not consider walking and cycling within their responsibilities, and there is often a disconnect within transportation departments between large-scale infrastructure investments and projects and “softer” people-oriented projects, such as pedestrian planning. As will be discussed, the call for more integrated transport, which has become more pronounced over the last 20 years, has led to more planning of projects that have a multimodal character.

With the post–World War II introduction of more commercial airline use and, more recently, the advent of low-cost airlines, air travel routes and airport capacity is managed separately. In shipping, too, both passenger and freight ships are planned for and managed separately. With increasing calls for integration across modes and for modal shift away from air to rail, or car to public transit, it is likely that in the future there will be a need for much closer and considered planning across modes, but at the present time, this separation of interests is a dominant feature of how transportation planning operates on the whole.

The primary foundation for road-based planning and decision making for several decades was the “predict and provide” tenet. An extremely significant investment was made starting in the 1950s in developing highway infrastructure, along with predicting where people would drive and how much, through running sophisticated transport models; this became the chief measure for planning transport projects to cope with demand. The primary

emphasis on delivery of projects has been economic in terms of providing transport infrastructure through the least-cost option, but also with consideration for maximizing the economic output that could be derived from a particular infrastructural investment over a given time period.

When road congestion became an increasing problem, the dominant solution was to plan and build increased road capacity to keep up with escalating demand. Since the 1980s, the approach of building more roads as a way out of the problem has been called into question, not only because such transportation planning predominantly focuses on those with access to private vehicles—and further marginalizes those without access—but also because increasing capacity has failed on the whole to deal with the rising demand and congestion. Additional capacity has actually induced further demand.

Expansion and Efficiency

One of the primary principles of the predict-and-provide approach was expansion, and transportation professionals over the past 70 years or so have been rewarded for successfully planning and implementing expansion projects. Similarly, conventional transportation planning would conceive of efficiency as a flow-of-traffic consideration (that is, a transport system would be understood to be more efficient if the vehicle speeds were increased).

This conception is clearly incompatible with the use of the term *efficiency* as referring to the need for more fuel-efficient vehicles and systems; these have been considered a priority for transportation planning, as well as for politicians, because of increasing environmental and health concerns among the public that have been highlighted over recent decades.

Indeed, the very nature of what is expected of transportation planning and politics is becoming very different from the conventional ways in which policies have been developed and transport systems produced during the 20th century. A broader array of stakeholders are participating in and contributing to the policy and planning processes in a manner that has not always been the case.

Politics and Pork Barrel Projects

It is fair to say that extremely strong influence is exerted over transportation planning and politics by industry lobbies that have been developed over decades to protect and promote business interests.

The intrinsic link between transportation and economic growth makes the relationship between transportation and business a very involved and complex one. Restricting transport flows and mobility is perceived as equivalent to restricting fiscal prosperity, and one of the significant and fundamental challenges faced by the transportation sector is how to decouple growth from transport demand. This, by definition, means that business has a strong voice in planning future transportation activity across all modes.

The automobile industry and the oil-and-gas sector lobby are just two of the most vocal and powerful examples of the commercial interests that exert significant influence over the transport decision and implementation processes. Businesses protect their own corporate interests and strive to make sure that government investment occurs and money gets spent on transport projects that meet or serve their particular interests.

One example of this complicated relationship is demonstrated by so-called pork barrel politics, which refers to financial investments being made to serve the interests of particular politicians or voters in return for their support through votes or monetary contributions.

Such tactics, while often difficult to prove because of the opaque decision-making processes that deliver transportation projects, highlight the increasingly complex interrelations between local, metropolitan, regional, and federal policy makers, and businesses and politicians. The “Big Dig” in Boston, Massachusetts, and the “Bridge to Nowhere” in Alaska are recent examples of transportation projects accused of being funded through pork barrel politics.

There are also certain high-profile examples where the dominance exerted by business has had significant, long-term impacts on the transportation landscape. This phenomenon is not new. In 1949, for example, several companies involved in the acquisition and subsequent removal of streetcar and electric train systems in American cities were convicted of conspiring to monopolize interstate commerce. Some commentators claim that such deliberate attempts to destroy transit systems in many cities was a key contributor to the automobile dependence witnessed across the United States since the 1950s.

The importance of gaining consensus from an increasing number of stakeholders in the delivery

Planning for biking or walking trails like this one at Wave Hill in the Bronx in New York City are typically managed by local authorities. Many transportation planning departments do not consider walking paths a part of their responsibility.

of transportation projects should not be underestimated. Just as the social and environmental impacts of transportation have been highlighted in the past few decades, so, too, has attention been drawn to the closed decision-making processes through which transportation investments and policies are made.

The power and influence of the corporate lobby should not be underestimated because it is one of the primary barriers to delivering alternate, sustainable transportation infrastructures. However, there are indications that the shift required to diminish business' disproportionate influence over transportation planning regimes and practices—and to make the system more accountable and democratic—has begun.

Participatory Planning Processes

As increasing calls are made for environmental and social considerations to be integrated into

transportation planning and policy implementation, transportation planners, policy makers, and politicians are being asked to fundamentally alter the way in which their decisions are made. This means that project successes can no longer be judged on the size of expansion, the cost of a development, or how fast traffic will accelerate.

Transportation planning increasingly needs to introduce a broader array of modes—walking, cycling, transit—into any development, and it needs to offer up space currently dedicated to the car to alternatives. Planning also needs to consider efficiency in terms of the least environmentally impactful way to get around and to consult with different communities and social entities, as well as businesses, to ensure that well-being and quality of life are considered alongside the bottom line.

Decision-making processes must become more transparent, and there needs to be consensus, or at least dialogue, between previously disparate groups of society in order to ensure that transportation planners do not keep trying to build their way out of gridlock, but instead try to provide sufficient infrastructure for alternative modes and to encourage their use.

There is a need for denser communities and to reduce the number of vehicle miles traveled. This presents a huge challenge for transportation planners, but it also emphasizes the need for planning to be holistic. Land use planners and transportation planners need to work more closely together to create long-term visions for communities that are integrated, connected, and resilient to environmental changes.

There is a need to think more broadly; transportation should be connected better with housing, health, planning, environment, energy, industry, and other policy areas. Most policy in these areas has been made in isolation and has resulted in a very fragmented, energy-intensive, inefficient, and unequal landscape in transportation and society.

Greater public participation is required across departments and across different levels of government to develop processes to redress the lack of balance that comes from primarily economically focused decision making, and to begin to move toward a more robust, longer-term perspective that runs independently of election cycles.

The entrenched shortcomings of the current transportation planning system are being

perpetuated with every funding cycle that invests in new roads to promote economic development. Multimodal transport can address health, transport, business, and housing issues, but not without an adequate amount of attention from politicians over a longer time horizon.

Transportation Policies, African

Transportation is considered a backbone of development, especially for the African continent. However, from a transportation perspective, the region would be perceived as not having enough road networks as well as lacking transportation policies. The lack of roads, especially rural roads, is viewed as a major physical constraint on mitigating poverty in the continent.

Africa is a continent with diverse culture composed of numerous countries. As diverse as the population is, the transport systems of Africa also exhibit a significant contrast in coverage and efficiency. For example, in 2011, the country of Chad had only 128 miles (206 kilometers [km]) of paved urban roads, while Tunisia, South Africa, Namibia, and Botswana each boasted over 3,107 miles (5,000 km) of paved urban roads.

Sub-Saharan Africa has a much lower density of paved roads than any other region in the world. It has only 127 miles (204 km) of roads per 386 square miles (1,000 square km [km²]) of land area, with only one-quarter paved. This compares with a world average of 587 miles (944 km) of roads per 386 square miles (1,000 km²) of land area, with over one-half paved.

The spatial density of roads in sub-Saharan Africa is less than 30 percent of the next-worst-provided region, South Asia, with one-half being paved, and only 6 percent of North Africa, with two-thirds paved. Traveling from one African country to another sometimes requires transiting through a European city by air. Apart from the problem of an inadequate and ill-maintained transport infrastructure, the continent is burdened with institutional hurdles, including cumbersome administrative and custom, procedures, corrupt officials and staff, lack of transportation policy, and a list of other deficiencies.

However, there are recent improvements in the transportation sector. Cities of some countries in Africa are exhibiting remarkable overall economic growth and this is reflected in the transportation sector. For example, in Addis Ababa, the capital of Ethiopia, the city's performance in the transportation sector has been so remarkable that the total road length grew from 845 miles (1,360 km) in 1998 to 1,983 miles (3,192 km) in 2010—that is, 135 percent growth in a period of 12 years.

Also, in the southern part of Africa, each country has been taking initiatives to rehabilitate, upgrade, and maintain existing road networks, as well as to construct new roads. For example, in Lesotho, the road network is constantly being expanded and upgraded, especially with the Lesotho Highlands Water Project, as development of the road network begins to access the more remote areas. In Madagascar, reforms and rehabilitation are taking place through the Transport Sector Program. In

Mozambique, the Roads and Coastal Shipping Program led by the World Bank has made developing the internal transport system a priority.

There are still several challenges for Africa's transportation industry. Although the major problem is lack of transportation policy that guides development, there are also poor institutional frameworks and lack of technical and financial resources.

On the technical side, serious problems of early cracking in bituminous pavements are frequent, especially in sub-Saharan countries, as well as rutting of paved surfaces not long after their construction. The explanation of these phenomena may sometimes be found in the choice of a weak road structure and sometimes in poor workmanship. Related to this, corruption of some African officials and technicians plays a role as well.

Civil unrest and border wars have caused disruption in the progress of road network improvement. Conflicts and wars in many countries have ruined the efforts carried out in the transportation sector.

Since their independence, almost all 43 sub-Saharan countries have been involved in civil wars or wars with other countries, and they have suffered from serious problems of internal disorder. The prolonged civil wars in some countries resulted in significant damage to road and rail networks, and the effects continue to be felt despite current initiatives to rebuild the networks.

Brief History

Africa's modern transportation infrastructure evolved during periods of colonial influence that focused on the development of transportation that facilitated links with Europe, other colonial holdings (for example, India), and trade routes within Africa that served colonial purposes. As a result, Africa is characterized by limited internal linkages, with only major cities designated as international gateways (seaports) to serve foreign markets.

Colonial authorities paid little or no attention to road building. For instance, in the case of French West Africa, there were hardly any roads outside a few urban areas in the region in 1914. The colonial powers invested almost exclusively in railways, which brought them economic benefits by transverseing the vast expanses between their designated places of commerce. Their need to minimize cost led them to build only those roads and streets that were absolutely necessary for colonial governance.

Because colonial powers recognized the importance of their physical presence throughout the colonies as a critical element of control, they proceeded to build a limited number of roads linking some hinterland areas to the colonial government centers. In the area of air transportation, very few airports were developed in Africa during the colonial era, and their purpose was primarily to link the colonies to “master” nations. Little, if any, efforts were made to link African cities by air.

Even several decades after independence, the transportation infrastructure of African countries didn’t show a sign of remarkable growth for many years, and there was no single transportation policy to guide the development of transportation infrastructure.

There are a number of reasons for sluggish growth in Africa, including poor economic and political performance, topographic conditions, and administrative incompetence. However, in recent years, with the help of the global financial institutions and the involvement of China, many African countries are exhibiting a remarkable growth in the transportation industry.

Sub-Saharan Africa Transport Policy Program

If there is one program that defines Africa’s (especially sub-Saharan Africa’s) transportation policy, it is the Sub-Saharan Africa Transport Program (SSATP). Originally called Sub-Saharan Africa Transport Policy Program, the organization started with a small group of African and international engineers and policy makers who were deeply concerned with the poor condition of the region’s road network.

Funding had long been a problem. Despite some nations having invested billions of dollars in road network funds, these nations were running out of money, and by the early 1980s, only 20 percent of the classified road networks were in excellent condition. Another conundrum for poor nations in the region was that they could not afford even the refurbishment of their existing networks, let alone help fund the construction of an extensive road network of the entire region.

Unfortunately, countries with deteriorating road networks would economically decline and poverty would increase. To address these challenges, Sub-Saharan Africa Transport Policy Program founders devised policies, such as institutional arrangements and capacity building, to stop the unproductive

cycle of road building, collapsing, and rebuilding for African countries.

In 1986, the founding group members met at the United Nations Economic Commission for Africa (UNECA) to develop a program that would address the neglect of the region’s road networks. The 1987 inaugural meeting in Oslo, Norway, led to the creation of the International Advisory Committee (IAC), which was a joint committee of the World Bank and UNECA. Offices were located in Addis Ababa, Ethiopia. However, program operations stalled as a result of funding limitations until 1988, when the organization relocated to the World Bank’s offices in Washington, D.C., and renamed itself the Sub-Saharan Africa Transport Program.

In its early days, the SSATP addressed a wide spectrum of issues, such as road maintenance, railway management, low-volume roads, rural travel and transport, development of agriculture and transport, taxation in transport, and many other issues. The program attracted several agencies from African countries and some international agencies. These stakeholders in a short time limited the range of the program to focus on policy issues.

By 1992, the program was implemented through seven components: Road Maintenance Initiative (RMI), Rural Travel and Transport Program (RTTP), Urban Mobility (UM), Trade and Transport (T&T), Railway Restructuring (RR), Human Resources and Institutional Development (HRID), and Transport Data (TD). RMI is meant to facilitate policy reforms resulting in sustainable maintenance and financing of public roads. RTTP is designed to better the livelihood of rural people by improving access to basic goods and services.

UM’s goal is to support and facilitate the provision of safe, efficient, and less polluting transport in cities of sub-Saharan Africa. T&T is designed to reinforce the international competitiveness of sub-Saharan African economies. RR is to help countries establish efficient and financially sustainable railway enterprises. HRID focuses on capacity building for policy reforms. Finally, TD is to provide information systems to support policy preparation.

The founding nine member countries, supported by small groups of donors, requested the UNECA and the World Bank to continue serving as executing agencies through the seven components. Membership grew from nine to 17 member countries in the 1990s.

The RMI component was the main attraction to the SSATP because its goal was to bring roads to the marketplace. Toward the end of the 1990s, African countries felt the SSATP was too donor-oriented, leading to funds being earmarked for specific projects that were geared toward donors' interests.

With fluctuating finances and weakening leadership in SSATP, African countries felt increasingly marginalized. Donors were also frustrated with the lack of management reporting, and they did not sufficiently recognize the program's policy principles aimed at poverty reduction. The concerns of African countries and donors were confirmed in the 1999 management review, and all parties concluded that there needed to be an improvement in the management framework of the program.

UNECA and donors gathered in 2000 to conduct a detailed analysis of the program. Conclusions of the seminal meeting changed the program, resulting in a new mission statement, a new governance framework, the setting up of an executive board, the formation of a ministerial advisory group, and the recruitment of a full-time program manager. In 2001, further review was conducted on five African countries impacted by the program, and recommendations were made for more African involvement in program management.

These recommendations led to the implementation of national and African regional coordinators based in Africa. Hence, SSATP became a stronger partnership with a sounder governance structure. By 2003, 30 African countries were engaged in different components of the program, and donor confidence was restored. The RMI and RTTP were the most popular of all the components. By 2006, the number of members increased to 35.

The governance framework of the SSATP is designed to govern management and program operations. The executive board acts as the program's guardian, moneymaker, and publicist, with members representing stakeholder constituencies.

The Constituent Assembly, which is a collection of donors, selects and guides the primary management team. The team is facilitated by the World Bank in offices located in Washington, D.C.; Nairobi, Kenya, and Yaoundé, Cameroon. Also, the team is supported by a network of SSATP coordinators in every member country.

Finances are channeled to a multidonor trust fund managed by the World Bank. The SSATP

annually holds a stakeholder meeting to review progress, discuss best practices, be advised by the ministerial advisory team, and support dialogue regarding policy progress and its effects.

From a coordination approach, the program's framework is to introduce programs at a country level, endorse SSATP policies and practices for dialogue regarding national policy, and to carry out program activities. The national coordinator leads the process and is able to request assistance from experienced individuals from other sectors for logical advice on policy and strategy. This type of coordination framework hinges on governmental backing and involvement in a sector-wide dialogue concerning all stakeholders.

Since the program's implementation, especially in the last decade, SSATP reports that countries have economically improved. Ten of the 48 sub-Saharan African countries have had economic growth in excess of 5 percent each year since 2005. There is no doubt that improved transport has contributed significantly to Africa's growth.

The social landscape has improved with many more people having access to health centers and more children able to go to school. The SSATP has a distinguished history of supporting information gathering, analysis, and dissemination. This has led to development of principles, themes, and areas of focus that have had a substantial impact on individual countries' transport policy formulation and implementation.

Some of the impact is being seen with the recent program resurgence and widening influence on the policies and operations of countries, regional economic organizations, aid agencies, and international organizations, such as the World Bank, UNECA, and the European community. On an overall program level, the SSATP is focusing efforts on national transport policies and programs that support poverty reduction strategies—specifically, on clarifying the role of transport in achieving the goals of other sectors, such as health, education, and agriculture.

The influence of the principles and themes championed by SSATP on transport-sector development has been strong and consistent. For instance, the influence can be clearly seen in Ethiopia, where an agriculture-led development plan triggered a comprehensive road sector development program (RSDP), which enjoys the support of many donors.

The RMI principles—ownership, stable financing, responsibility, and good management, all supporting the theme of commercialization—have been central to the Ethiopian RSDP. Similar principles championed by the RTTP, such as ownership, good management, and adequate funding, have been applied not only to policy, but also to actual or pending improvements in many country programs that enjoy wide support.

Transportation Policy in Northern Africa

North African countries include Algeria, Egypt, Libya, Morocco, Sudan, Tunisia, and the Moroccan territory of Western Sahara. Literature on transportation policies of north Africa is usually meshed with the Middle East because of cultural and social resemblance. With few exceptions, the region's cities don't have well-organized transport systems, and have suffered from a lack of transportation policy while transport demand is constantly increasing.

Recognizing the problems and their negative impact on the economy and society, national governments and local authorities in nearly all the north African countries have now embarked on far-reaching structural reforms regarding the building of major infrastructure projects. Based on the amount of information available, this section will briefly discuss on transportation in Algeria, Egypt, and Morocco, based on UITP (International Association of Public Transport) reports.

In Algeria, each of the 48 provinces contains a transportation department for urban transportation and land transportation. Shortly after independence (1962), Algeria had a well-developed transport network, especially with the merging of the rail systems Tramways Algeriens (TA) and Chemins de Fer Sur Routes d'Algerie (CFRA), now known as L'Entreprise Publique de Transport Urbain et Suburbain d'Alger (ETUSA, Algiers Public Transport Company).

Algiers's first urban transport map of the regional and urban company network CFRA dates back to 1908. Until 1987, urban transport services were almost entirely provided by public operators that generally came under the control of local authorities. The deregulation of the sector was immediately followed by the proliferation of private operators and an overall increase in supply (doubling of the number of minibuses and taxis, with more than 22, 000 taxis for the six main cities,

half of which operate in Algiers). This led to a drop in the market share for public operators who had lost their monopoly.

In the capital of Algiers, over the past few years, a major urban infrastructure construction and refurbishment program has been instituted by the provinces of Algiers. Moreover, the Algerian government has launched an ambitious five-year development plan. Accordingly, the Ministry of Transport prepared a public urban transport plan and a master traffic plan designed to resolve the problems concerning the transport sector in Algiers and to meet the traveling needs of the population.

In Morocco, the Ministry of Home Affairs is in charge of transportation at the national level. The Economic and Social Division manages it for the ministry at the city level through various public corporations or contracts awarded to private carriers. Through these channels, Morocco is addressing the segments of the region's cities that have suffered from a lack of transport policy, despite the fact that transport demand is constantly increasing.

Research indicates that the country has agencies and departments for urban transportation that govern the transportation system, but effective transportation policy is still required. After understanding the problems and their impacts on the economy and society, the Moroccan government and local authorities have now started to implement structural reforms and to build major infrastructure projects.

In Egypt, the four main urban locations are Greater Cairo, Alexandria, Port Said, and Suez. Urban public transport systems exist in these areas and in the main cities and administrative capitals. Transport networks in Egypt can be divided into intercity networks and urban networks. The intercity networks include rail networks, highway networks, and inland waterway routes along the Nile River and its branches. Urban networks include local roads, subway (Metro) networks, urban railway lines, and some routes for ferryboat services. Passenger services in Egypt can be divided into two categories: regulated services provided or monitored by the Ministry of Transport, and services provided by private operators (not planned or regulated by the Ministry of Transport).

Cairo Master Plan

According to the Ministry of Transport, the Greater Cairo Region (GCR) , as the main urban region of Egypt, will experience increasing transport

problems in the future. Because of this recognition, the Strategic Urban Development Master Plan of the Greater Cairo Region (a policy and planning document) in 2008 identified many projects that needed to be implemented, including new infrastructure projects and redevelopment projects.

The master plan identified many actions, policies, and projects that need special attention, such as minimizing usage of private cars, giving attention to parking problems, and developing new systems for increasing parking lots. The master plan also included actions such as promoting park-and-ride, implementing traffic management solutions, applying bus priority lanes and segregated lane systems, especially along the newly planned corridors, and developing ring roads around the main cities and communities.

Among the focuses of the master plan were incentives and governmental support for private-sector involvement in public transport services, with coordination and integration with the existing modes; development of a vehicle inspection system for assuring safety and environmentally friendly trips; development of comprehensive planning for both urban and rural areas; promotion of demand management rather than increasing transport supply; and limiting the role of the government in organizing and regulating the transport business.

Conclusion

Sub-Saharan transportation is mainly shaped by the Sub-Saharan Africa Transport Policy Program (SSATP). There has been a 30 percent improvement in the number of roads classified as good under SSATP management, but government corruption, civil unrest, and poor workmanship still hinders progress. SSATP is criticized for a lack of African leadership and management. This was somewhat corrected through framework restructuring in mid-2000, which yielded greater donor confidence.

One other point to note is that transportation was excluded from (or barely mentioned in) the United Nations' Millennium Development Goals (MDGs). The MDGs, initiated in 2000 to alleviate poverty, do not encompass targets to lessen the transport constraints on the poor. This is a concern for many because Africa, more than any other continent, is known for its vast, sparsely populated rural areas, lack of transport infrastructure, and rural poverty.

The relative immobility of sub-Saharan African rural dwellers and their poor access to social and productive services and markets is especially pronounced. North African countries are just beginning to have a transportation policy that guides urban transportation growth and development.

For the last decade, an increase in urban populations and their accompanying transportation problems have prompted several countries to come up with transportation master plans and implementations are now under way.

Transportation Policies, Asian

The nature of transport problems varies among world regions. Asian countries in particular face severe problems of congestion, maintenance, upgrading facilities, and degradation of the environment due to high levels of noise and air pollution. For instance, India, with over a billion people in 2011, of whom more than 30 percent reside in urban areas, faces transport problems such as accessibility to jobs, businesses, and education and recreation centers.

The government of India implemented a National Urban Transport Policy in 2006 with the objectives of encouraging integrated land use and transport planning in all metropolitan cities, improving access of business to markets, introducing intelligent transport systems for traffic management, reducing pollution levels via changes in traveling behavior, and promoting greater use of cleaner technologies.

The Indian government also enunciated a transport development project of completing a "Golden Quadrilateral" highway network connecting India's four largest cities—Delhi, Mumbai, Kolkata, and Chennai—thereby forming the four vertices of a quadrilateral. The program was announced in 2001 at an estimated cost of \$11 billion by the National Highways Authority of India, under the Ministry of Roads, Transport and Highways. Four other metropolitan cities—namely, Bengaluru, Pune, Ahmedabad, and Surat—will also be served by this network; thus the agricultural, industrial, and cultural centers of India will be connected.

This network development plan will provide several benefits such as improved accessibility to major cities and ports; easy movement of people, freight, and products; industrial and job development in smaller towns and cities; provision to farmers of market access for their exports; indirect demand for cement, steel, and building materials for real estate development; and, finally, the impetus for truck transport.

Most Asian countries face severe problems of congestion, and therefore government and transport planning agencies adopt transport demand management (TDM) measures. In China the rapid growth of the economy during the past three

decades has led to urbanization and motorization, in turn exacerbating problems of traffic congestion, urban sprawl, energy consumption, and rising air pollution. Policy analysts argued for an increased supply of public transportation, although during the 1990s and 2000s the response was an increased supply of roads. This was expected to mitigate the problems of urban mobility, accessibility, and congestion.

For example, in Shanghai the proportion of expenditures on public transportation increased to more than 80 percent during 2010, while the rest of the country increased the share by 6 percent during 2003 and 2009. There has also been an enhanced focus on construction of high-speed rail to ease the movement of people and thus increase connectivity.

There still remain several problems such as lack of integration of high-speed rail with the bus system in cities and lack of coordination between metro rail and bus systems because multiple agencies manage the two systems. Policy makers need to implement policies deterring the usage and ownership of private cars by raising parking fees and adopting bid-auction mechanisms for vehicle registration.

For instance, Singapore implemented a bidding system for vehicle purchasing rights and electronic road pricing policies for restricting automobile dependency and, thereby, reducing private vehicles on roads. Until the 1990s, policy makers in Singapore utilized fiscal restraints on car ownership, such as import taxes, registration fees, and an additional registration fee which is equivalent to a percentage of the import price of the car. However, during the 1980s the government provided discounts on the sale of old and used cars older than 10 years old in the scrap market, thereby driving the prices of used cars above their original value.

This development rendered car ownership and usage policies less effective. In turn, it displeased the public since the speculative car traders made windfall gains at the expense of the larger public. A lesson for future car ownership policy making is to be wary of the potential of creating speculative asset markets for cars that might generate social inequity.

Similarly, in the Seoul metropolitan area in South Korea, the congestion problem is severe; the government tried supplying more transport roads to ease the congestion problem but to no effect. The problem has been very severe in the Namsan

Rickshaws, hand carts, tuk-tuks, motorcycles, and cars all vie for the right-of-way in New Delhi traffic. Concern about increasing traffic congestion and its environmental and health consequences has been an important research agenda in the past decade. Recently, there has been a growing realization that based on current policies, transport trends are not sustainable.

tunnels, which connect the city with the central business district. During the mid-1990s, the Seoul metropolitan government implemented toll fees on private cars with fewer than two persons. This increased bus and subway use and increased the average vehicle speed in the downtown area.

In sum, a combination of transport demand management such as toll fees, parking fees, expensive car registration, gasoline taxes, and higher taxes and fees for car ownership can perhaps mitigate road congestion, thereby alleviating environmental problems as well.

Transportation Policies, European

The objective of a Common Transport Policy (CTP) for Europe can be traced back to the Treaty of Rome, which was signed in 1957 and established the European Economic Community (EEC). Transport was one of main areas of common policy of the treaty, but some of the ideas behind a common transport policy for Europe can be traced back even further in time. In 1951, for example, the Treaty of Paris established the European Coal and Steel Community (the forerunner of the EEC) and contained a chapter on transport.

Despite being a common area of policy for more than 50 years and featuring in all key European treaties, transport policy developed relatively slowly, especially up to the mid-1980s, which is generally considered to be a turning point in European transport policy making. Before this time, many member states were unwilling to relinquish control of national transport markets and had very different views about the role of transport policy vis-à-vis the economy and society. Both the policy focus and the level of activity in policy making were quite different between these two periods (1950s to mid-1980s and mid-1980s to present).

Transportation Policy 1950s to 1980s

The first phase of community initiatives, from the late 1950s until the mid-1980s, was primarily aimed at establishing common standards, harmonizing member states' regulations on transport, and establishing common conditions for transport services. In the 1960s, a detailed transport policy program was developed, but this soon proved unacceptable to many member states that ascribed to a range of political ideologies. For some member states, the proposals were considered too liberal; for others, the proposals were judged to be incompatible with their situations.

In spite of the high ambitions of many leaders, attempts to create an overarching common transport policy in the 1960s were blocked at every turn. By the early 1970s, as a consequence of these experiences, the European Commission switched to a more pragmatic approach to transport policy, where many transport-related issues were pursued separately in order to find solutions in specific areas

and specific modes. Consequently, progress on the development of a common transport policy for Europe was slow and piecemeal.

In 1974, the scope of the CTP was broadened by the European Court of Justice, which ruled that while the specific provisions establishing the CTP applied only to inland modes, aviation and maritime transport were nevertheless subject to the general provisions of the European treaty. However, it was not until a decade later that policies in these areas were developed.

Slow progress in the development of a European CTP up to the mid-1980s was primarily a result of the inability to reconcile the opposing interests and regulatory approaches of the member states under the condition of unanimous voting in the European Council. At the outset, the CTP was hampered by contrasting regulatory approaches and conflicting economic interests of the member states.

Half of the six founding members of the EEC—France, Germany, and Italy—had national policy regimes characterized by a high degree of state intervention in transport markets, and so they were traditionally skeptical of a liberal transport regime at the European level. Those countries viewed transport policy as a means to accomplish regional, industrial, and social policy goals. The Netherlands, in contrast, was a pronounced supporter of a liberal approach to European transport policy, having seen benefits for Dutch transport industries under a more deregulated system.

Another explanation for slow progress in the development of the CTP is that, because various international bodies and agreements on transport already existed, the development of a European CTP was not always regarded as absolutely necessary. In 1983, the European Parliament, which had generally supported the European Commission's efforts to develop the CTP, took the Council of Ministers to the European Court of Justice for "failing to introduce a common policy for transport and in particular to lay down the framework of such a policy in a binding manner," as required by the Treaty of Rome.

In a landmark ruling in 1985, the European Court judged that the Council had indeed "failed to ensure freedom to provide services in the sphere of international transport and to lay down the conditions under which nonresident carriers may operate transport services in a Member State," and was therefore

in breach of the treaty. This effectively marked a watershed moment for European transport policy.

In addition to the “inactivity verdict” from the European Court of Justice, other political factors helped contribute to a subsequent acceleration of policy making on the CTP. One of the most important other developments was the publication of the *White Paper on Completing the Single Market*, which contained around 300 legislative measures to be taken, many of which had implications for transport. The white paper argued that

the right to provide transport services freely throughout the Community is an important part of the Common Transport Policy set out in the Treaty . . . and that the development of a free market in this sector would have considerable economic consequences for industry and trade.

Thus, the evolution of the CTP in the mid-1980s was a consequence of a combination of institutional developments supporting the acceleration of the policy-making process and a change in the political ideology in some member states.

European transport policy was incorporated into efforts to achieve the internal market, and was seen as a precondition for an effective market because it would provide links between producers, markets, and consumers. These developments, taken together, amounted to a major transfer of transport policy powers from nation-states to Europe.

The foundations of contemporary common transport policy were laid between 1985 and 1992 under the impetus of the single market program. The late 1980s and early 1990s saw the introduction of a raft of measures as the European Single Market was established. Policies shifted from standardization (harmonization) to liberalization, and a number of transport sectors were targeted for deregulation (for example, shipping, air transport, rail, road haulage). In addition, European funding was granted for a number of new transport infrastructure projects from the late 1980s onward via the Structural Funds, especially the European Regional Development Fund, which became more available to transport projects after reforms in 1988.

The mid-1980s also heralded the first appearance of European environmental policy, which had important implications for transport policy. The

Eurostar trains, shown at Waterloo International railway station, run through the Channel Tunnel between the United Kingdom and France and Belgium. Most Eurostars can carry 750 passengers, which is roughly equivalent to five Boeing 737s.

1986 Single European Act contained new articles on the environment, and the 1992 Treaty on the European Union (the Maastricht Treaty) further underlined the position of environmental policy in relation to transport policies (and other sectors).

At the same time, the issues of transport safety and transport infrastructure were given more prominence in the 1992 treaty, thereby extending the scope of a common transport policy for Europe. One of the centerpieces of the new transport policy agenda was the development of pan-European transport infrastructure, the Trans-European Transport Network (TEN-T).

Trans-European Transport Network

One of the main ideas behind developing the TEN-T was to underpin and strengthen the creation of Europe's internal market and to reinforce economic and social cohesion. The objective was to integrate national networks and modes of transport, link peripheral regions of the European Union to the center, and improve safety and efficiency.

While the policy foundations for the TEN-T are contained in the 1992 Maastricht Treaty, the idea of a common infrastructure policy for Europe was not entirely new. Since the early 1980s, calls for a trans-European network were being made by the European Round Table of Industrialists (ERT), one of the most powerful business groups in Europe, representing some of Europe's largest automobile and oil companies.

One analyst called the ERT the "spiritual progenitor" of the TEN-T, and the beginnings of the policy can be traced to a 1984 ERT report titled "Missing Links," which proposed three major European transport infrastructure projects: (1) EuroRoute, an English Channel link between England and France; (2) Scanlink, a plan to fill in the road and rail gaps between Norway, Sweden, Denmark, and northern Germany; and (3) a trans-European network of high-speed trains.

Having defined infrastructure problems in terms of missing international infrastructure links, the ERT then sought to set the agenda for action and, in 1991, called for a better network of roads (especially to overcome Alpine and Pyrenean mountain barriers), high-speed railways, and air terminals in a report titled "Missing Networks—A European Challenge." The ERT's 1991 report formed a blueprint for the TEN-T proposals introduced in the 1992 Transport White Paper, published just a few months later.

The formal decision to develop the TEN-T was made by the European Parliament and Council in 1996. Since then, the plans for the network have undergone several revisions as a result of the expansion of the European Union and budgetary changes. The guidelines for the development of the trans-European transport network, adopted in 1996, provide the general reference framework for the implementation of the transport network and for identifying projects of common interest.

A list of 14 major infrastructure projects (the "Essen projects") was included in the 1996 guidelines as the first priorities to be completed before 2010. In 2001, the TEN-T guidelines were amended in various respects, including greater emphasis on the multimodal dimension of the TEN-T, by bringing seaports and inland ports fully into the network.

The guidelines were amended again in 2004, primarily in order to take account of EU enlargement and the expected changes in traffic flows. The 2004 guidelines included a list of 30 priority projects of

European interest: the original 14 Essen projects plus an additional 16 projects to be completed by 2020. More than half of these 30 projects concerned rail transport (17 projects), another four concerned road transport, four were multimodal in nature, three concerned water transport, one concerned an air transport project, and one was a global navigation and positioning project (Galileo).

In 2005, the TEN-T was presented as a key element for increasing economic competitiveness and employment. Since 2006, the Trans-European Transport Network Executive Agency (TEN-T EA) has had the responsibility for implementing and managing the TEN-T program on behalf of the European Commission.

In general, TEN-T projects are funded to a major extent by national governments, but they also receive funding through various European community financial instruments (for example, Cohesion Fund in eligible countries and European Regional Development Fund), as well as loans from the European Investment Bank.

Although the majority of the priority projects concerned rail and the fact that more than half of the TEN-T special budget line went toward rail, European financial support for TEN-T projects is nevertheless skewed toward road transport, particularly under the more sizable Cohesion Fund and EDRF budgets. Consequently, the TEN-T policy has aroused opposition on environmental grounds with critics saying it merely promotes road use at the expense of parallel modes (rail) and undercuts sustainability objectives.

TEN-T policy has also been controversial because of relatively low economic impacts and high environmental impacts, particularly when it comes to biodiversity associated with the development of infrastructure along some parts of the network. The policy also has been criticized because it does not provide an effective contribution to the EU's climate change objectives, and because it increases the demand for transport by adding new routes and increasing the speed of travel.

Although presented as a strategic, integrated, pan-European policy, TEN-T essentially represents a loose collection of nationally or regionally important infrastructure projects. According to the European Commission's own 2009 review of the TEN-T policy, the planning of the network "has not been driven by genuine European objectives."

Others have argued that the EU's role in transportation policy has been mainly limited to acting as a catalyst to the process by identifying the common European interest of projects, and operating as a facilitator in negotiations between European states and subnational governments as well as private-public partnerships, construction companies, and service operators.

Transportation Policies, North American

In the United States, transportation policy is carried out by the U.S. Department of Transportation (USDOT), created in 1967; transport had previously been a function of the Department of Commerce.

The Department of Transportation includes a number of federal agencies that formulate policy and regulations for different areas of transportation in the United States: the Federal Aviation Administration, the Federal Highway Administration, the Federal Motor Carrier Safety Administration, the Federal Railroad Administration, the U.S. Maritime Administration, the National Highway Traffic Safety Administration, the Pipeline and Hazardous Materials Safety Administration, the Research and Innovative Technology Administration, the Saint Lawrence Seaway Development Corporation, and the Surface Transportation Board. Until 2003 when the Department of Homeland Security assumed them, the Transportation Security Administration and U.S. Coast Guard were also part of the USDOT.

Standards, protocols, and guidelines for use in highway design and construction are set by the American Association of State Highway and Transportation Officials (AASHTO), which has operated since 1914 and has a membership that includes the DOTs of every state, as well as Puerto Rico and Washington, D.C. AASHTO also provides some of the data used in formulating transportation policy and is the primary source of data on road structural design and materials reference.

The Transportation Research Board (TRB) advises the federal government, including federal

agencies, the USDOT, Congress and congressional committees, and the president, on scientific and technical matters related to transportation policy. It is one of the six major divisions of the National Research Council, a scientific advisory body administered by the Institute of Medicine, the National Academy of Sciences, and the National Academy of Engineering.

The TRB's annual meeting brings together over 10,000 transportation researchers and professionals, and throughout the year research is pursued by more than 200 task forces and committee groups. One of the TRB's programs is the National Cooperative Highway Research Program, established in 1962 to promote the research of solutions to highway problems, including efficiency, maintenance and repair, engineering and construction, and safety and security. The program draws on the funding of state transportation departments, each of which is expected to contribute 5.5 percent of their research funds.

Canadian Transport Policy

In Canada, transportation policy is developed by Transport Canada and the Canadian Transportation Agency. Transport Canada, established in 1935, develops Canadian transportation services and the regulations and policies that govern them, including the Canadian Coast Guard, the Railway Safety Act, the Marine Transportation Security Act, and the Transportation of Dangerous Goods Act. It also oversees motor vehicle safety in accordance with the 1971 Motor Vehicle Safety Act, and accessibility for people with disabilities to railroads and other services.

Transport Canada also has jurisdiction over Canadian waterways and civil aviation, and operates the nation's publicly owned airports. As in the United States, transportation infrastructure has been generally underfunded in recent decades, in part because of growing conservative factions seeking to limit government spending and in part because of the emergence of new forms of infrastructure that have attracted funding at transportation's expense, notably high-speed telecommunications and Internet infrastructure.

The Canadian Transportation Agency is a tribunal given decision-making power in certain areas related to transportation policy. It is responsible for the licensing related to federally regulated

transportation, ensuring that national transportation systems are accessible to people with disabilities and others, and resolving complaints about federally regulated transportation.

Transport Policy in Mexico

In Mexico, transportation policy is formed by the legislature, the president, and the Secretariat of Communications and Transportation, the federal agency responsible for commercial transportation regulation (as well as regulating broadcasting). Regulation of civil aviation falls to the Directorate General of Civil Aeronautics, which is principally concerned with aviation safety.

Mexico City, one of the largest cities in the world, with unique transportation and infrastructure challenges, was awarded the 2013 Sustainable Transport Award by the Institute for Transportation and Development Policy (ITDP), an American non-governmental organization that provides assistance and advocacy for sustainable transportation in the Americas, Asia, and Africa.

The ITDP helped develop Mexico City's Bicycle Master Plan program, which gave the highly populated city a vast network of bicycle paths designed for connectivity to other transportation modes in order to encourage bicycle use for practical, everyday purposes, rather than just recreation. The Bicycle Master Plan was one of many recent additions to Mexico City's transportation policy. Metrobus, the citywide transit system, was expanded with new lines, while Ecobici, the city's public bicycle system, was expanded significantly after an initial pilot period.

Street parking regulations were also reformed, and new traffic management policies were adopted in order to attempt to calm traffic for greater safety. The ITDP also assisted Mexico City in revitalizing the city's Historic Center, including building a bus line from the Historic Center to the airport, improving street maintenance, instituting new parking management systems, and reorienting the area toward bicycle and pedestrian traffic and public transportation.

The city has undertaken a long-term plan to attempt to reduce vehicle emissions, having for a long time suffered some of the world's worst vehicle-related air pollution. The growth of the Mexican middle class has resulted in skyrocketing automobile ownership in a country with few regulations

about greenhouse gases or vehicle emissions. In 2011, for instance, despite the worldwide financial crisis, the total number of cars in the country increased by 11 percent.

The changes enacted in Mexico City in 2012 helped transform it from one of the worst commuter cities in the world to one of the best, thanks to a greatly improved transportation system, improved public spaces, Ecobici and the Bicycle Master Plan, a new nine-mile subway line called the Golden Line, and various pedestrian-friendly measures. It is the first time that transportation policies have actively encouraged forms of travel other than the automobile.

Improvements to parking management resulted in a reduction in “cruising for parking,” the time spent looking for a parking space in the city, which fell from an average of 13 minutes to three, while emissions fell for the first time in years. Most federal efforts in Mexico still favor motor vehicles, however, with about 84 percent of 2012 federal expenditures on urban mobility spent on motor vehicle infrastructure such as roads, bridges, and parking lots.

Transportation Policies, South and Central American

According to the United Nations, approximately 75 percent of the population in South America currently lives in cities, and the urban population is

expected to rise by more than 80 percent by 2020. This urban population is highly dependent on public transport, performing the majority of their daily trips in buses or metros. However, economic growth and greater access to financial credit in the last 20 years in the region has caused the number of vehicles per person to rise from 0.08 to 0.17. In this context, key issues that have motivated transport policies in the region are air pollution, traffic safety, and traffic congestion.

Although transportation policy presents a diverse picture throughout South America, some of the most important measures implemented in the recent past are road space rationing, improving public transport systems, implementing fuel taxes, and expanding the capacity for private automobiles.

Road Space Rationing

The most common transport policy in South America consists of restrictions on the use of cars at certain times and on certain days. This has been implemented since the 1980s in Chile and Mexico, and later in other countries, such as Brazil, Colombia, and Ecuador. Although the key motivation has been air pollution mitigation in the majority of these cases, easing congestion in its own right is also a direct or indirect expected result for policy makers.

The implementation of these policies is diverse. In Bogotá and Medellín, Colombia, and Quito, Ecuador, cars are banned from circulating one weekday at peak hours, whereas in Mexico City cars cannot circulate during any business hours once a week. Similarly, Santiago, Chile’s space rationing program bans cars from circulating in the metropolitan area once a week, but applies only to those cars without a catalytic converter.

Further uses of these programs include extending the ban to motorcycles and raising the number of days that cars cannot circulate, such as in the case of Medellín. Most of these space rationing policies are implemented year-round or, at least, in the colder months of the year, especially if the main motivation is environmental.

However, space rationing has also been implemented as an emergency measure only when air pollution reaches critical levels, as in the case of the state of Rodizio in Brazil. In these situations, banning has sometimes been extended to public transport trucks and higher numbers of cars, such as in Santiago.

Despite the extension of space rationing as a policy throughout South America, the evaluation of its impacts on air pollution and congestion is mixed. In the case of air pollution, some cases showed no evidence of air quality improvements, such as in Mexico City; others suggest important decreases, such as in the case of Quito.

Although several evaluations have shown a decrease in congestion levels, it is not clear to what extent these effects are offset by an increase in car ownership and use and by the rearrangement of daily routines. In addition, assessing these policies is less clear in the light of improvements in clean technology, such as the increasing number of cars with catalytic converters and the improvements in fuel quality. Yet, space rationing is a policy still in place in most of these cities with the dual purpose of improving air quality and congestion.

Public Transport Systems

The majority of public transport systems in the region have high levels of deregulation, resulting from such factors as the free market policies of recent decades, the strong influence of current operators and unions, and the historically passive position of governments at all levels.

As a consequence, public transport systems in the region are predominantly independently operated, with fierce internal competition, which has led to excesses of supply, the lack of integration of services, and negative externalities, such as air pollution, congestion, and accidents. Pressured by those problems, some governments have taken action to improve public transport systems.

Some policies have been directed toward building or expanding current metro systems, and, because of the high investments needed, only few major cities in five countries (Chile, Colombia, Venezuela, Argentina, and Peru) have running metros. The exception is Brazil, whose population size justifies public transport investments in several cities.

Given the scarcity of funds throughout the region, though, most public transport policies have been directed toward improving bus systems in terms of regulation and operations. In fact, successful policies have led to an institutional transition from independent and deregulated markets to public and government-regulated services. Some examples of these policies are Curitiba's master plan in

Brazil; Transmilenio in Bogotá, Colombia; Transantiago in Santiago, Chile; and other related initiatives in Ecuador and Peru.

Curitiba's master plan, developed in 1965, was a pioneer public transport initiative in the region, consisting of a highly connected network of more than 50 miles (80 kilometers) of exclusive bus-lane corridors and several feeder lines, with very high levels of service standards. The plan is aligned with the city's land use planning, which promotes denser use along the corridors. The system is a public-private joint venture; the administration of the system consists of one entity managing the operations and revenue and another central entity handling strategic and long-term decisions.

Following Curitiba's successful experience, Bogotá's Transmilenio system has been gradually implemented since 2000. Transmilenio consists of several trunk lines that run in separated lanes and feeder lines that cover important parts of the city. The system was financed at the municipal and national levels. The program has been successful in professionalizing the services, substantially improving bus speeds and reducing air pollution.

Motivated by these other experiences, Transantiago was implemented in 2007 in Santiago de Chile, following a system of dedicated-lane trunk and feeder buses that integrate the whole city's public transport system. Improvements included contactless smart cards and a financial administration separated from the operators. Transantiago was initially designed so that no subsidies would be needed for the private operators.

In contrast with Transmilenio's implementation, the Transantiago system went from regulated to deregulated overnight. However, at implementation, there were not enough dedicated lanes, which had negative consequences in terms of bus frequencies and travel times. Those issues, in addition to the underestimation of the level of cultural change that the new system involved, negatively impacted transit ridership. After revising the initial design, mainly through government subsidies, and changes in the operations, the system's level of service and ridership has improved, as did air pollution.

Other countries have pursued more limited policies with varied results. Examples of these systems are Metrobus in Mexico City and Metrobus-Q in Quito. New regulatory regimes have been put

in place in Argentina in order to turn independently owned cooperatives into formal commercial enterprises, with mixed results.

In the case of Lima, Peru, the complete deregulation introduced in 1990 led to an increasing number of trips by motorcycle taxi, and a degradation of the system into one of the oldest public transport fleets in the region. High-capacity busways in dedicated rights-of-way and a new central transit authority have arisen in recent years to overcome these issues. In the case of Caracas, Venezuela, the metro is not integrated with the minibus system, but in La Paz, Bolivia, public transport still mainly consists of single minibus owners and passenger operators.

Fuel Taxes

A less common transportation policy is fuel taxes, partly because of the resistance from the general public and partly because of the availability of cheap oil in some countries, such as Venezuela. One of the exceptions is Chile, where the so-called Specific Tax was implemented in 1986 as a way of collecting money after the earthquake that hit the country's central area the year before. The tax is still in place, but with unclear objectives, which range from improving environmental and economic efficiency to collecting money for transport infrastructure. The effect of this policy is hard to measure because there are no explicit transfer mechanisms to ensure that the collected money is indeed used for tackling these goals.

Expanding Capacity to Private Automobiles

The increasing mobility and auto ownership levels, and consequent congestion levels, experienced in several cities in the region have put pressure upon governments not only to improve public transport systems or restrict the use of cars but also to expand capacity for private automobiles. The limited amount of available funds for achieving this goal has encouraged different forms of public-private partnership arrangements.

One example is the implementation of five urban highways in the core area of metropolitan Santiago in the 1990s and 2000s, which were financed through a private-public partnership with public bidding for four interoperable free-flow electronic tolling highways. The level of service for cars improved substantially, although at a high investment cost.

Current Trends and Challenges

Despite these policies, the increasing mobility needs in South America require intensifying and extending the regulation and modernization process for public transport systems throughout the region. In fact, these challenges are becoming important not only in city capitals but also in other cities within each country. The implementation of bus rapid transit in several cities in Colombia and other innovative transit systems, such as the cable cars in Medellín, are some current answers.

Current governance structures in the region are in general very rigid in terms of encouraging policies that could integrate land use, transportation, and environmental dimensions, all within a multimodal perspective. This integrated perspective requires learning from the experiences of some of the projects delineated here, even though they may be contradictory when the provision of infrastructure for cars is weighed against improvement of public transport.

There is still resistance among politicians from the region to implementing other transportation policies that have been implemented in other parts of the world, such as congestion pricing for roads and other travel demand-and-supply management tools.

Transportation Policy, U.S.

Transportation policy in the United States is primarily carried out by state and local agencies, with some input, guidance, or earmarked funding provided by the federal government. The U.S. Department of Transportation (US DOT) and its agencies also set relevant regulations (as do a handful of other federal agencies—the Environmental Protection Agency, for example, regulates some aspects of transportation planning that bear on the emissions in vehicular exhaust).

State-level planning helps better coordinate local development while also addressing issues beyond the purview, or sometimes the interest, of the local government, such as the impact on other communities, the environmental consequences, and social and economic ramifications on a larger than local scale. In short, state-level planning looks at the “big picture.”

It is often suggested that federal-level planning could do likewise, but the federal government’s guiding hand is not often felt, despite the public’s perception that the ratio of federal to state power and involvement is greater than it used to be. A number of issues either fail to be resolved or have unwanted consequences because of state-level thinking without more federal involvement.

For instance, the Greater Boston area encompasses not only the Massachusetts communities surrounding Boston but parts of New Hampshire and Rhode Island, and there has long been a plan to extend “T” service (the Boston-area subway) to southern New Hampshire, both for commuters (of which there are many in the region) and shoppers. Both states agree they will benefit, but disagreements over which state funds how much of each stage of development, land acquisition, and construction have repeatedly stalled the project.

Beyond the Rational Planning Model

Modern transportation planning has historically followed the rational planning model, which consists of a straightforward model for making transportation planning decisions. The rational planning model begins with an overview of the relevant data followed by the identification of the problem to be solved. This is followed by stages that propose

a goal, identify and assign weights to the criteria by which plans will be evaluated, generate various alternatives, create a model of the situation, and determine the optimal decision to reach the defined goal.

The rational planning model is sometimes faulted for assuming that sufficient information about the problem can be obtained and that the consequences of various options can be foreknown. Even apart from this, the process is time-consuming and can be taxing on resources in the information-gathering phase.

In part due to environmentalism, but also due to changes in American thought and in the academic environment in which transportation planners receive their training, the rational planning model no longer has the dominance it once had. Instead, planners, especially younger planners, often have a multidisciplinary background and are as likely to draw on sustainable development models or behavioral psychology or social justice concerns in formulating their plans.

Beginning around the 1960s, transportation planning has increasingly been treated by many as a component of larger plans or a way to promote social, economic, or environmental policies. Transportation plans may actively encourage walking or bicycling, for instance, or the use of car-share services over car ownership, which tends to cut down on unnecessary car usage. The overall trend in transportation planning in the United States, as in the United Kingdom and South Korea, is to expand the scope of planning beyond finding the most affordable and efficient means of addressing a transportation problem toward a planning approach that encompasses and synthesizes multiple goals.

This means, for instance, integrating transportation planning with land use planning, environmental concerns, health concerns, and concerns about access to resources. For instance, modern transportation planners take more specific notice of the effects on the elderly or disabled of possible transportation plans; they are concerned about resource problems afflicting particular populations or neighborhoods, like food deserts and the effects of gentrification; they have for some time now wrestled with the effects of suburban sprawl. In short, they are occupied with planning transportation projects that address the needs of American society, the environment, and the economy.

This is a significant change from an approach that previously was occupied mainly with building new roads and new routes, whereas today, a major project of the transportation planners in, say, Boulder, Colorado, is not to build new roads but to widen and pave the shoulders of existing roads, in order to increase the city's bikeable miles.

The Example of Boulder, Colorado

Boulder worked at increasing the city's bicycle access for over a decade before launching 2011's bike share program, which for a low membership fee makes bicycles available at public stations throughout the city. The bicycles are available for up to one hour with no additional fee beyond the cost of membership; this is to encourage fast turnover and the use of bicycles less for recreational rides around the city and more for the practical trips that would otherwise be made by bus or car.

The Boulder bikeshare program, B-Cycle, is a good example of the concerns of modern transportation planning. The program is expected to generate a profit for the city and has no real economic toll; it takes into account the reasons for travel as well as the means; it encourages a particular means both through incentives (the convenience of using an available bicycle you do not need to store at home) and by making it easier to use (by making the city streets easier to bicycle); its benefits include economic benefits to the citizenry (more Boulder residents can now give up car ownership, or drive less and use less gas, or if already carless have access to opportunities they might not otherwise), health benefits to the bikers (particularly reducing risks of heart disease and diabetes, major health problems facing the country), and environmental benefits by reducing the emissions associated with driving. (It's easy for riders to quantify these benefits, as the software that manages the B-Cycle system uses unique user profiles that monitor burned calories, biked miles, and carbon offset.)

A year after launching, B-Cycle received a federal grant for expansion. In 2013, when Boulder was hit by the 100-year flood that claimed several lives, there was no time to evacuate B-Cycle's equipment. Despite devastating flooding throughout much of Colorado, and several of the bicycle stations being completely submerged, the damage to the bicycles and the equipment used to rent them

to pass-holders was minimal. Within a couple of weeks, 19 of 22 stations and nearly the full fleet of bicycles were back online.

One of the bicycles was painted green (instead of the retro cherry red of the rest of the fleet), and throughout the following month, \$5 was donated to flood relief efforts for every ride logged on the green bicycle.

2009 Economic Stimulus

When the \$787 billion economic stimulus plan was passed in February 2009, nearly \$30 billion of it was allocated to transportation investments. The money was disbursed to state governments and metropolitan planning organizations (MPOs) with little earmarking—transportation projects could be chosen by the states and MPOs as they desired, for the most part. It was well understood that there was a nationwide backlog of bridge and road repairs, even apart from the funding needs of current and future public transportation systems.

Approaches varied considerably. Some states spent most of the money on building new roads rather than repairing existing ones, with one-third of the total money going to new-capacity roadway projects. Because building new roads involves a time-consuming planning and land acquisition process, these projects took longer and created fewer jobs.

Less than 3 percent was spent on public transportation, despite ridership reaching an all-time high and numerous public transportation agencies cutting routes and services because of the recession. Less than 1 percent was spent on bicycle and pedestrian projects, though it is possible that this should be considered in light of their lower cost compared to motorized infrastructure. The distribution of funds was different from state to state, of course. Vermont's "fix it first" transportation policy meant nearly all of the state's money went to repairing or upgrading existing infrastructure, with a small portion spent on public transportation and nothing on new roads.

Arkansas, at the other extreme, spent 81 percent on new roads and other infrastructure and nothing on public transportation, leaving little for repairs, despite the fact that only 38 percent of its roads were rated as being in good condition by the American Association of State Highway and Transportation Officials.

One of the cities to receive a stimulus grant for transportation was the 45,000-resident town of Normal, Illinois, which received \$22 million to build a transportation hub. Normal's hub locates trains, city buses, regional bus services, and taxis in a centralized building as part of a redevelopment effort centered in the uptown area, which was made more accessible for pedestrians, bicyclists, and public transportation. City officials advocated for the next federal transportation reauthorization bill to encourage similar projects for similarly sized cities throughout the country.

Organization

Which agency is responsible for transportation policy and addressing the issues that impact transportation planning varies from jurisdiction to jurisdiction. In particular, local governments vary considerably in size, complexity, and type. Some small communities in New England still make policy and budget decisions through town meetings, for instance, while other communities vote on ballot issues, and still others defer most of the decision making to elected or appointed officials.

At the state level, numerous departments may be involved. Their names may vary, and some states may subdivide duties in a way that does not exactly correlate to the typical state Department of Transportation (DOT) discussed here, which is responsible for developing and regulating transportation networks in the states, including roads, mass transit, public transportation, and pedestrian and bicycle travel.

Ideally, the department has an overall strategic plan for the role it plays in the growth and development of the state's communities, and for the state to encourage a balanced transportation system that meets local needs while being affordable. Federal law requires state departments of transportation to develop long-range plans but leaves their specific content to the states themselves.

Transit-Oriented Development

Because states' needs vary so much, so do the activities of transportation departments. New Jersey's overall plan is largely centered on transit, and it is the most prominent state to adopt an approach to transit planning called transit-oriented development. Transit-oriented development, which is also the policy model of the San Francisco and Salt

Lake City, Utah, metropolitan areas, is a model of development that focuses on increasing access to public transportation and increasing transit ridership—a particularly appealing approach in densely populated areas where traffic congestion has both social and economic consequences, even apart from environmental concerns.

The New Jersey transportation department distributes a handbook on transit-friendly land use policies to local New Jersey governments, in addition to operating a transit villages program, a public-private transit development program, and a program helping home buyers qualify for their mortgage by reducing their transportation expenses.

Transit villages are residential developments surrounding a transportation hub, with a small retail business component to help serve the shopping needs of the community. Transit villages are essentially residential developments optimized for public transportation users, in much the same way the suburbs that spread in the 1960s and 1970s were residential developments designed for frequent drivers (and in most cases, families with a minimum of two cars).

New Jersey has developed transit villages in Mercer County, Somerville, Hamilton Township, and along New Jersey Transit's Northeast Corridor, all under the name of the Transit Village Initiative. The Transit Village Initiative was founded in 1999 to offer an annual \$1 million grant to a municipality ready to begin a transit village project. Twenty-four different transit villages have been funded since then. Transit villages have also been developed in Miami, Florida, which has developed housing complexes around Metrorail stations, and Portland, Oregon, as part of that city's overall more sustainable and transit-friendly transportation plan. For further details see the entry on Transit-Oriented Development.

Transportation departments also typically oversee and coordinate the repair and maintenance of existing infrastructure, which throughout the country is badly in need of fixing. Despite the fact that half of the country's roads and bridges are poorly maintained, two-thirds of transportation funds in the country are used to build new roads instead. As mentioned above, Vermont is one state that has adopted a "fix-it first" approach to its transportation policy, assigning the highest budget priority to the repair of existing roads and to preventive maintenance.

Complete Streets

Transportation departments may also elect to adopt a “Complete Streets” policy, which was adopted as a federal policy goal in 2000. Complete Streets are streets that are equally accessible to residents with varying modes of transportation and level of ability, including motorists and transit riders, pedestrians, and bicyclists, taking into account the needs of the elderly, the disabled, and children. This means ensuring safety, paving shoulders or adding bike lanes, adding adequate and frequent crosswalks, and ensuring frequent-enough snow plowing and shoveling, as well as adequate drainage for rainwater.

Further, streets need to properly connect for multiple modes of transportation—sidewalks should not dead-end at the edge of a neighborhood, and bike coverage needs to be sufficient to allow bicyclists access to most of the city.

California and Illinois have passed laws requiring Complete Streets policies in transportation planning, while states like Colorado and Washington have worked to come closer to the Complete Streets goal. While Complete Streets plans can be adopted on the local level, street connectedness, bicyclability of neighborhoods that straddle town lines, and proper interlinkage of municipal transit systems can be difficult to ensure without state oversight. Typically, technical assistance programs and funding assistance are made available to local governments in order to help them do their part to meet statewide policy goals. For further details see the entry on Complete Streets.

Other Planning Departments

Transportation departments are not the only departments involved in state transportation planning, of course. Agricultural departments can set policies that guide the balance between preserving agricultural land so that citizens can obtain some of their food locally, and making land available for development. The Agricultural Security Area Program established in Pennsylvania in 1981, for instance, allows towns and cities to designate agricultural security areas where farms are given special privileges from government policies, encouraging their long-term planning.

Economic development departments can guide economic development by restoring Main Streets and downtowns, organizing brownfield cleanups,

and encouraging public transit, and can set policies to encourage commercial developers to make their neighborhoods pedestrian and bicycle friendly. Energy departments can support walking and bicycling by expanding commuter tax credit programs to include energy-saving commutes. Housing departments can provide incentives or tax credits to people who live near work or public transportation stops and are thus less likely to drive. Illinois reverses this, giving tax credits to businesses that are located near public transit and residential neighborhoods.

Education departments have a land use component to their planning activities, and many states assign, for instance, acreage minimums to schools, or other zoning requirements. Education departments can assist with planning where to locate or relocate schools in ways that serve the state’s transportation goals, while also coordinating school transportation policies, encouraging walking or bicycling to school, and establishing Safe Routes to School programs.

Colorado, for example, receives federal funding for a Safe Routes program that is distributed to support programs to relieve traffic congestion and high-speed zones in the vicinity of schools in order to create more routes by which children can walk to school.

Transportation Research Board

The Transportation Research Board (TRB) operates as one of the divisions of the National Research Council, which is a part of the National Academies, a private nonprofit organization, which includes the National Academy of Sciences, the National Academy of Engineering, and the Institute of Medicine. The National Research Council provides independent expert advice and research services to the U.S. government, the scientific and engineering communities, and the general public. The work of the Transportation Research Board is carried out by 7,000 experts in the field of transportation. TBR's work is funded by the U.S. Department of Transportation, state departments of transportation, federal agencies, and various organizations and individuals.

History

In 1920, the National Board on Highway Research was created to serve as a clearinghouse for research on all aspects of highway technology. Five years later, the name of the board was changed to the Highway Research Board (HRB), which continued to coordinate research on highways. Daily activities were carried out by standing committees, and the group issued regular publications and held an annual convention.

In the 1950s, for the first time, the Highway Research Board began engaging in its own research projects, responding to research needs as they arose. In 1962, the HRB initiated the National Cooperative Highway Research Program (NCHRP) and extended the scope of the HRB's activities. In 1974, the name of the board was again changed, and the HRB became the TRB. In the 1980s, the TRB became involved in conducting research on national transportation policy for the first time. In the 1990s, the TRB's scope was further extended when the board was given responsibility for overseeing the Transit Cooperative Research Program and Long-Term Pavement Performance studies.

In the 2000s, the TRB manages Innovations Deserving Exploratory Analysis (IDEA) programs and continues to engage in cooperative projects that go beyond the scope of highway research, dealing with research issues such as airports and transportation of freight and hazardous materials. A major

focus of the TRB's current work is implementing the second Strategic Highway Research Program.

Committees and Task Forces

In January of each year, the TRB holds an annual meeting in Washington, D.C., that attracts 10,000 transportation experts from around the world. Approximately 3,000 presentations and 1,500 peer-reviewed papers provide insight into current research in all modes of transportation. The annual conference also provides an opportunity for committees and task forces to conduct meetings. Throughout the year, the TRB conducts other conferences and hosts workshops on transportation issues.

When the National Board on Highway Research was established in 1920, there were only three standing committees charged with providing and disseminating research on American highways. By the 21st century, the number of standing committees and task forces had grown to 1,200. The work of these groups is carried out by more than 4,000 transportation experts. The committees and task forces are organized into 11 groups. Six of these groups focus on the functional aspects of transportation, particularly on highways. The remaining groups deal with public transportation, freight, rail, aviation, and marine research issues.

Organization

Leadership within the TRB is provided by the executive committee, which is made up of members appointed by the chair of the National Research Council (NRC). Committee members include experts from the top tiers of the transportation industry and governmental transportation agencies and academicians who specialize in transportation research. The executive office of the TRB is charged with overseeing all programs and activities, working with committees and panels, preparing reports and various publications, conducting outreach, serving as a resource center, and furnishing staff support to the executive committee and the subcommittee for NRC oversight.

The TRB is organized into five major divisions: Technical Activities, Studies and Special Programs, Cooperative Research Programs, Strategic Highway Research Program 2, and Administration and Finance. The Technical Activities division is responsible for supporting standing committees and task forces; conducting field visits to transportation

agencies and academic institutions; and planning various meetings, conferences, and workshops. The TRB inherited the Marine Board in 1999 from another NRC unit and assigned it to the Technical Activities Division. The function of the Marine Board, which was created in 1965, is to coordinate research on all elements of maritime transportation with that of other disciplines.

The Studies and Special Programs division is responsible for convening special committees involved in policy studies, and reviews and prepares synthesis reports that come under the province of Cooperative Research Programs. The Studies and Special Programs division also maintains the Transportation Research Information Service (TRIS) database and provides library services.

The Cooperative Research Programs division is charged with overseeing the National Cooperative Highway Research Program, the Transit Cooperative Research Program, the Airport Cooperative Research Program, the National Cooperative Freight Research Program, and the Hazardous Materials Cooperative Research Program. The responsibility of the Strategic Research Program 2 division is managing a goal-oriented, short-term program that was created to gather research on advancing highway performance and safety. Financial and administrative support for the TRB is provided by the Administration and Finance division.

Cooperative Projects

Some of the most important work carried out by the Transportation Research Board involves research conducted in conjunction with other agencies and groups. As part of the first Strategic Highway Research Program (1987–93), the Innovations Deserving Exploratory Analysis (IDEA) Program was established to recognize innovative research in transportation. Subsequently, three separate IDEA programs were created. The National Cooperative Highway Research Program of the IDEA is supported by the Federal Highway Administration (FHWA) and operates in conjunction with the American Association of State Highway and Transportation Officials (AASHTO) to focus on innovative and nontraditional research in the areas of highways and intermodal surface transportation.

The IDEA Transit Program is supported by the Federal Transit Administration and the Transit Development Corporation. The focus of the IDEA

Transit Program is on technologies, methods, management processes, materials, and systems in the transit sector. The IDEA Intelligent Vehicle/Highway Systems (IVHS) Program is supported by the Federal Highway Administration and the Department of Transportation's National Highway Traffic Safety Administration (NHTSA). Its focus is on innovative research in IVHS technologies in reference to highways, vehicles, intermodal surface transportation, and transit systems.

In 1997, the TRB's Cooperative Research Program and the Committee on Transportation Safety Management began working with AASHTO's Standing Committee on Highway Traffic Safety, the FHWA, and the NHTSA to identify 22 focus areas essential to improving safety on U.S. highways. A pool fund was established to implement the recommendations that addressed such subjects as roadway and infrastructure needs, drivers, vehicles, emergency medical services, and the traffic safety management process. The comprehensive plan produced by this cooperative effort came to be known as the AASHTO Strategic Highway Safety Plan. The Transportation Research Board subsequently published the *NCHRP Report 500: Guidance for the Implementation of the AASHTO Strategic Highway Plan*.

Transportation Statistics and Databases

Transportation statistics and databases offer a mixed blessing to practitioners in the field. By considering system requirements, components, and performance through statistical analysis, transportation managers and policy makers can make better-informed decisions.

On the other hand, to avoid becoming swamped by the rising tide of incoming data, these same professionals are compelled to learn new ways to handle the databases generated by their transportation domains. The information can help experienced managers balance operational data against strategic policy goals—but only if their mastery of the data exceeds or keeps pace with the sheer volume of data and allows them to separate signal from noise.

Complex Settings and Uses

Understanding transportation systems in their diverse modes, settings, and purposes is a complex task. Many data sets and statistical bodies are linked to a large number of different markets, demographic groups, and geographically distributed activities. Some of the transportation modes are operated in extremely competitive markets, while others are over-consolidated or monopolistic; some are highly regulated, others less so. Some are dominated by private operators, some by public, still others by hybrid forms of ownership and operation. Each of these scenarios and contexts tends to create statistical data of varying degrees of accuracy and accessibility.

Some transportation systems require great fixed capital assets and infrastructure. Others represent emergent modes or intermodal forms that will be altered in their effect and scope by virtue of their increasing connection to the existing networks

The Moving Ahead for Progress in the 21st Century Act (MAP-21) is a bill to govern U.S. federal transportation spending. It was passed by Congress and then signed by President Barack Obama on July 6, 2012. Accurate statistics play a paramount role in the success of such bills and in achieving goals such as alleviating traffic congestion and reducing the federal budget deficit.

of separate technologies and their intelligent and opportunistic use of available data.

Among the kinds of data that provide inputs, or raw statistics, for database management systems to compile and sort are supply and demand, current and future needs, local and regional economic and demographic trends, monopolistic structures and competitive forces, fixed costs and variable prices. To make sense and practical use of this wealth of often counterweighted data, information management systems must not only take it in and sort it, but the type and scope of outputs also must be considered in terms of form, size, flexibility, searchability, and appropriateness to the policies in place and the tasks that need to be completed.

Another type of metric is also involved: the human factor. For utility in this area, a database must help its users grasp and interpret such “fuzzy” data as transportation customers’ willingness to pay, their perceived value of service, and their perceived value of alternate or comparison services. Ideally, a database can handle humanistic input variables—such as lower travel cost or the seasonal desirability of particular destinations—in such a way as to generate output that can help transportation administrators and managers predict shifts in demand over the near and long term and plan accordingly.

Available Resources

There are several categories of statistical and database resources that apply to nearly all transportation planning needs and operational applications. These in general comprise (1) university and college departments; (2) federal, regional, state, and municipal transportation and public policy agencies; (3) professional and trade group best-practices boards; (4) social science and public advocacy institutions; and (5) private enterprise technical departments. An example of each includes:

1. Inter-University Consortium for Political and Social Research, which has published and archived such works as the Metropolitan Travel Behavior Survey Series, originally conducted by the University of Minnesota using federal funding. The series includes individual and mass transit data collected in 22 metropolitan markets across the United States, ranging from the Baltimore Travel Survey of 1977 to the Midlands Tomorrow Household Travel Survey of 2006–2007, covering the Columbia, South Carolina, metro area.
2. National Transit Database (NTD) of the Federal Transit Administration, established by Congress as the chief repository for transit system data, statistics, surveys, and reports. The NTD imposes uniform reporting standards across its data sources and their outputs, and takes in comprehensive reports from nearly 700 urban transit system operators across the country, as well as a number of rural system operators. The NTD comprises data mainly from rail and bus systems.
3. Institute of Transportation Engineers, which makes available information on operational standards, technical specifications, and related data as it applies to the design, engineering, upgrading, and troubleshooting of transportation infrastructure signaling, monitoring, and management technology. Datasets are developed and provided on topics as technically driven as “Object Definitions for Dynamic Message Signs” and those as broadly sourced as “User Comment Disposition Summary for NTCIP 1203 v02,” which indexes field data and troubleshooting results on a variety of technology installations.
4. American Public Transportation Association, an advocacy group that underscores the benefits of public transportation policy advances through its print and online publication of data such as its quarterly “Ridership Report” on public transit usage; its Public Transportation Investment Background Data series, covering the financial statistics on transit funding sources and the outcomes projected from scaled levels of investment; and such data-rich reports as its “Trends in Public Transportation Vehicle Fleets” report.
5. Bombardier Insight, a division of the corporate communications unit of this transportation manufacturer, which through its Expert Library project provides widely sourced statistics on a range of topics

under the headings of mobility, urban congestion, economy, society, and productivity. The online-based Expert Library comprises internal data sets and graphics; survey statistics and analysis linked to news-gathering companies based in Asia, Europe, Africa, and elsewhere; academic reports; and data from such diverse bodies as the Railway Association of Canada, the United Nations Development Program, the British Council, and ClimateProgress.

Performance Management

Statistics and database management underlie the ability of transportation authorities to provide such information-intensive functions as active traffic management and dynamic pricing of tolls. They are also key to selecting, applying, and controlling the growing array of techniques applicable to multimodal and demand management, including smart growth planning, flexible dispatch systems, automated rolling stock direction, options for telecommuting, and on-demand car and ride sharing.

Areas that require continuing information appraisal and statistical report review include the decision-making process for providing the necessary levels of operating support functions, as well as the decision-support methods that provide intelligent means to implement and use performance measures and to continually refine management processes.

A great deal of this type of support can be considered under the rubric of performance management. For instance, the Federal Highway Administration (FHWA) Office of Operations has identified the principles and tools of performance management as essential to improving transportation mobility and efficiency in the United States—among the leading policy mandates of every transportation agency, whether operating at the federal, state, regional, or local level.

Reducing congestion, a fundamental metric of improving system reliability in any transportation mode, can tap a particular aspect of performance management often called mobility monitoring. This refers to identifying mobility-based system performance metrics, interpreting the trends that emerge from the data, and generating reports to inform

both policy makers and operational decision makers. In the process, FHWA stipulates, “Mobility and reliability measures are identified that communicate well to both technical and nontechnical audiences.”

The agency suggests that performance management mobility monitoring be tuned to measure and review the data that will be needed to answer certain questions as operations and operational conditions are modified over time. These questions ideally include the following:

- Where and when is the transportation system congested and/or unreliable?
- What operational improvements are working and where?
- What transportation improvements are needed and where?

As an example of the sensitivity to unique factors that must be accounted for in the data accumulation and evaluation for research of a given mode of transportation, the FHWA posits the example of a contrast in modes. In its consideration of the function of fully access-controlled highways (such as the interstate highway system), the FHWA notes that the essential goals of the system include mobility and speed-of-person and speed-of-freight movement.

This is in contrast to urban thoroughfares that must support a number of countervailing goals that are distributed across a number of quite diverse users, such as bicyclists, pedestrians, private automobile drivers, and mass transit users. Therefore, the creation and application of appropriate performance management statistical metrics must be structurally and contextually different for each of these modes.

Performance management systems are being developed for, and will continue to be refined to maximize the use of, the ongoing expansion of wireless sources that can provide real-time data from a plethora of originating points and in a broad range of statistical categories. Radio frequency identification (RFID) systems, smart card readers, mobile devices, and increasingly data-connected vehicles hold much potential to supply decision-making and performance-monitoring systems; yet they also hold the risk of overwhelming such systems, or disproportionately emphasizing information that is less than vital.

Nevertheless, performance data is likely to eventually become widely available for all modes, all links and intermodal stations, and most geographic locations. The FHWA plans to help manage the convergence of collection of data that, in addition to average speeds and travel times, would feature the more qualitatively tuned results such as day-to-day trip reliability, trip origin and destination, and traveler satisfaction. These metrics will obviously call for more sophisticated processing tools, including various amounts of artificial intelligence handling.

Toward this policy goal, the United States Moving Ahead for Progress in the 21st Century Act (MAP-21), enacted in 2012, enumerated performance management as a core element to make various individual and combined transportation modes in the United States more efficient, effective, and predictable. MAP-21 provided more than \$105 billion to fiscal year 2013 and 2014 budgets for surface transportation. Within these budgets, MAP-21 stipulated performance goal metrics on a national basis for the following:

- Safety
- Infrastructure condition
- Congestion reduction
- System reliability
- Freight movement and economic vitality
- Environmental sustainability
- Reduced project delivery delays

Governmental authorities active in each of these policy areas have been charged with devising ways to “do more with less.” This is a core tenet of MAP-21; the flip side of this policy priority is to apply advanced technology, smart systems, real-time feeds, statistical tools, and database analysis to provide the means to do so. As such tools themselves are currently in widely different degrees of development, and as they are constantly being reviewed and refined, this means the hunt for innovation will rely as much on judgment as on raw information.

Well-organized, searchable, and fully accessible data on system performance is key, but is in some ways only a beginning. Practitioners of transportation innovation must tap their data sources not only as a means of answering questions but as a way to gain insight into what the next questions will be.

Weighing Costs and Benefits

Among the more valuable findings possible from many transportation database instruments now applied across various transit modes are insights into which constituents win and which lose. Perhaps put less crudely, this question can be expanded to query who and what are the individuals, groups, metropolitan and rural jurisdictions, environmental ecosystems, economic sectors, and transportation programs and policies that stand to benefit from the implementation of a particular decision—and which among those parties stands to pay some type of cost.

Decision-making output derived from this set of questions generally has important influence on the reality and perception of changes to a transportation system as the ramifications of those changes are experienced by (1) individuals, (2) government bodies, (3) private operators, and (4) ancillary agents such as insurance providers.

Therefore, the diversity of database statistical modeling systems and their output are of concern, especially when seeking to contrast and compare decisions made across many different scenarios and when seeking some degree of uniform reliability about how various parties will be affected by transportation decisions.

A range of metropolitan planning organizations (MPOs) were surveyed by the Transportation Research Board (TRB) on the subject of what types of data modeling they employed in their travel-demand-forecasting role, and the TRB found “that there are considerable variations in the completeness and complexity of the models and data employed,” further noting that “MPOs vary significantly in the number of staff devoted to travel forecasting.”

In this study, the TRB reported that a large majority of the MPOs said that they utilize a four-step research model. This approach uses survey and other data to estimate future trips; it also statistically assigns those future trips to various travel modes. Seven of the responding MPOs surveyed indicated that they employ activity-based models.

This type of statistical modeling tends to be tied more closely to sociological elements, such as household makeup and traveler characteristics and behavior, and therefore activity-based models should in concept permit the MPOs to address policy questions that conventional four-step models

are especially ill suited to handle. For example, four-step models are not readily employed to handle the task of estimating the emissions effects of small transportation projects; they also would not be facile at linking data on these effects to air quality over all in a given statistical area. The more advanced, or subtle, database modeling techniques, of which activity-based models are one type, are needed to reliably estimate such outcomes.

System Effectiveness

One measure of the effectiveness of a database modeling tool is how much it helps operational managers and staff speed up good decision making by virtue of being presented with simpler choices. This is apparent in such systems as train rescheduling, where deviations from scheduled operations have immediate rippling effects that need swift detection, reaction, and resolution. Train dispatchers, through experience as well as trial and error, have built up a sound knowledge base that permits them to employ logical simplifying rules in order to judge deviations with a high degree of reliability and then to quickly make and implement decisions that resolve the conflicts stemming from those deviations.

Statistics-based decision support tools can help dispatchers in this process—but only if they can accurately and rapidly predict any cascading implications of the various solutions employed to resolve deviations. Software developers have worked on upgrading such tools by working with train scheduling personnel. Experienced dispatchers have been able to test these tools by filling in any blind spots the researchers might have had.

In just such a developmental experiment with Turkish State Railways, the dispatchers and software developers were successful in using genetic algorithms to supply conflict resolution solutions. In order to faithfully mimic the decision behavior of dispatchers within the automated operation of the software, the experimenters crafted artificial neural networks. Results were promising and lend insight to the expanding role that advanced statistical and database technology and techniques may hold in improving transportation problem-solving and decision-making challenges.

Transportation Studies

This field studies the movement of people and goods via alternate modes of transport, such as road, rail, water, and airways. It analyzes the transport system that facilitates the movement of commodities and its relationship with various dimensions of economic development such as economic growth, industry location, land use, sprawl, energy, pollution, and climate change. It is like any other factor of production and, hence, there is demand and supply of transport.

The means of transport provides a vital link among production centers, suppliers, and market areas. Transport is a derived demand and improvements in it are expected to be followed by economic development. It plays an important role in economic development by providing a unifying and integrating influence upon the economy.

This field is interdisciplinary, and has had a long-term symbiotic relationship with the disciplines of civil engineering and economics, thereby embracing the quantitative approach to build mathematical transport models. Further, it has been influenced by other cognate disciplines such as transport logistics, planning, geography, and geographical information systems (GIS).

Transport geographers study the spatial patterns of transport networks and nodes and how this eases the friction of distance, thereby shaping land use and settlement systems. During the 1950s, the advent of the interstate highway system in the United States connected cities and towns, made some places more accessible, and led to the demise of other locations.

North American geographers during the 1960s heralded the building of highways with quantitative modeling and applications to understand the spatial aspects of transport. The field received considerable impetus from the federal government in the 1970s because of its interest in regional transport policy issues such as railroad reorganization and abandonment, intercity bus deregulation, airline passenger transport deregulation, motor carrier deregulation, and energy and environmental problems related to transportation.

Study Areas for Transport Geographers

Transport geographers since then have worked in four major areas, focusing upon structure, growth,

and development of transport networks; spatial interaction; travel patterns; and GIS.

The network analysis research tradition took off in 1970 with the publication of R. J. Chorley and P. Haggett's *Network Analysis in Geography*. Transport analysts study nodes, links, networks, and systems. Links between nodes either by a single mode or several modes lead to the emergence of important nodes. Further, a pattern of links produces a network and the provision of a physical arrangement of transport infrastructure generates a transport system.

The relationship between transport network and development was examined for Ghana and Nigeria in the early 1960s. The conceptual model proposed the development of a series of coastal ports, followed by the development of a series of feeder lines, leading to extensive interconnection and the development of routes of dominance.

This model has been criticized for its oversimplification and several questions have been raised: How do developing countries make a transition from one stage to another in the development process? How far does the model represent the development needs of the host country rather than the aspirations of the colonial power? Are there overlaps with the models of transport development in developed countries?

The Airline Deregulation Act of 1978 in the United States put an end to the oversight by government of fares, routes, and market entry of private airlines. This policy change led to the development of the current hub-spoke network structure of air travel in the United States. Such a network configuration brings economic advantage to certain nodes (that is, the hubs), which become centers of commercial success while airports located at the extremities of a spoke face economic decline.

One author examined the changes in the centrality of hubs resulting from global airline industry deregulation. The analysis indicated that the hubs in the poorest developing countries, such as those in sub-Saharan Africa, became relatively inaccessible and isolated, while the emerging economies in the western Pacific Rim of Asia gained markedly in their accessibility.

There has also been interest in understanding the hub-spoke network as an outcome of a network design problem. Studies on network design have found theoretical reasons for the rise of hub-spoke

networks, the location of hubs, and their evolutionary trajectory. Clearly, the hub-and-spoke network has emerged as a distinct area of research in transportation studies in conjunction with location analysis and network design.

In transport geography, much of the research has examined spatial interaction ideas, such as complementarity, transferability, and intervening opportunity. Complementarity implies there is demand for a good or service in one region and an other region supplies it. Transferability implies the product needs to be shipped at an acceptable exchange rate or cost of transport. Intervening opportunity implies there should be a lack of an alternate source of supply or excess supply in relation to demand.

Several quantitative methods have been utilized to study transportation problems, such as the gravity model, entropy-maximization model, logit-choice models, and trip-chaining models. A family of spatial interaction models has been developed to construct predictive estimates of volume of flows between locations.

The flows in these models are a function of the distance between nodes, demand for goods and services among cities, and the ease of movement among various modes by alternate modes of travel. There have also been calls for an increasing role for modeling in the areas of land use, investment, pricing, and regulatory policies in response to increased traffic congestion in metropolitan areas. In transportation geography, this relationship among modeling, prediction, and planning has been exceedingly important.

Travel patterns and variations in them have interested transport geographers. Analysts have observed that travel patterns peak at morning and evening hours of the day. The movement patterns in rural areas reveal seasonal and weekly peaks. But the question that needs to be asked is, what factors explain the observed variations in urban and rural areas? And, are there differences in the movement patterns among male and female travelers in rural and urban areas?

The notion of job and housing balance became important as a strategy to address the suburban traffic congestion problem resulting from increased commuting between work centers in the central business district and the suburban fringe where people resided. Analysts have noted that if adjacent localities near employment centers had developed

affordable housing, less traffic would have been generated on highways.

In transportation planning, GIS is an information system specializing in the recording of digital information and managing and processing information that is spatially referenced. A branch of GIS applications specific to transportation is called geographical information systems for transportation (GIS-T).

The Bureau of Transportation Statistics (BTS) in the United States collates several databases related to transportation including network databases, surveys of human travel behavior, and studies of commodities flows. There are three ways to approach GIS-T and they are data representation, analysis and modeling, and applications.

First, data representation is the core of GIS-T research because data has to be represented in a way that can be readable in a GIS environment. A very important strength of GIS-T is that it can integrate both spatial and nonspatial data for purposes of display and manipulation. There are two basic data models of representation: object-based data model and field-based data model. The former model is suitable for features that are discrete and identifiable such as points, lines, and polygons. The latter model is suitable for features in geographical space that are continuous.

Within GIS-T, for instance, network analysis is represented by a set of nodes, interconnected by links. The object-oriented data model is suitable for transport applications. GIS-T also has developed several unique applications, such as shortest path and routing algorithm, spatial interaction models, network flow problems, facility location problems, travel demand models, and land use transportation interaction models. GIS-T has a wide variety of applications, including transport and logistics, transport safety analysis, transit planning operations and control, routing, and scheduling.

Logistics and Supply-Chain Study

Business logistics as a field of inquiry was born in the 1960s. It studies the movement of goods, products, and services from the production to the consumption and waste disposal stages in both forward and backward directions in order to maximize value addition and customer satisfaction.

Transport is an important component of the set of physical activities in the production process and includes such activities as supplying inputs to

manufacturing plants, warehousing services, and merchandising establishments. An efficient transport system is a precondition for business logistics because it improves overall efficiency, reduces operating costs, and promotes service quality.

An efficient transport system makes the product movable, improves regional efficacy, and enhances the competitiveness of production and sale of goods. The business literature on logistics and transportation has embraced the rise of just-in-time delivery, express logistics carriers, and the move to supply chain optimization, which reflects the importance of information on logistics.

Supply-chain optimization is a set of mathematical techniques applied to ensure the optimal operation of a manufacturing and distribution supply chain. This process entails placing inventory within a supply chain and the minimization of transport costs. This procedure entails the application of computer software and mathematical programming.

A supply chain can be represented in terms of network models where the supplier may own factories that manufacture component parts and ship them to customers, who are the assembly plants, located elsewhere for building and testing products.

Subsequent to the seminal publication of the 1959 book titled *Economics of Competition in the Transportation Industries*, the subfield of transport economics took off. This treatise by J. Meyer et al. addressed a comprehensive analysis of transportation resource allocation problems utilizing statistical techniques for empirical analysis.

Economics of transportation has broadly addressed themes such as demand, supply, investment, regulation, and the environment. Demand for transport has been studied mainly for estimating key parameters of the users of various transportation modes with respect to modal attributes such as price, quality of service, and speed.

Supply of transport has been concerned with the estimation of a firm's cost function (for example, the existence of scale economies in various transport industries). Such an analysis is useful in evaluating whether freight and passenger transportation services are provided at the lowest cost to society; further, it helps in identifying if one mode of transport has an advantage relative to another mode. Subsequently, cost function estimates provide insights to productivity growth in different transport industries.

Investment analysis is concerned with determining the net present value (NPV) of future streams of revenue and costs by discounting with a rate of return that calculates the marginal productivity of capital in alternative uses. Transport analysts were interested in controlling natural monopolies to ensure that passengers and freight would not be charged tariffs and fares priced higher than they could bear. Railways, for example, were known to discriminate against modes of transport serving the individual passenger and therefore needed to be regulated.

Finally, transport is a major consumer of energy and a source of pollution. The emission of hydrocarbons and the production and consumption of fossil-based fuels raises the question of long-term sustainability of current transport systems.

Transportation Surveys

A transportation survey is a data collection tool used to gather transportation-related information about individuals or groups. Transportation policy makers at all levels need sound data to make decisions about program design, policy choices, and accurate forecasting, as well as for effective monitoring and evaluation. Smart decisions for planning and implementing decisions about transportation require comprehensive, precise, and up-to-date data about travel demand, infrastructure condition, travel time reliability, the equity of access, and environmental impacts.

Transportation surveys of various types allow researchers to collect large amounts of information in a relatively short amount of time and to do so at a lower cost than other data collection strategies. Traditional survey methods have included paper-and-pencil questionnaires and interviews conducted in person, via mail, or by telephone, but advances in technology in recent years have changed the ways in which transportation data is collected and analyzed.

Types

Transportation data are related both to the spatial elements of a particular area and to the transportation network (roads and public transit). Land use surveys, those that study and record the ways

land is being used in a particular area, are an integral component of transport planning information requirements. Because travel is a "derived demand," meaning that it has no inherent value but only worth that rests in its facilitation of other activities, transportation researchers need information about the location and intensity of land use activities.

The transport system inventory survey also provides transportation researchers with vital information. The transport system connects land uses, and the volume and frequency of travel that occurs between land uses depends upon the quality and quantity of the transport system inventory. Thus, surveys of the transport system inventory, including both public and private modes of transport, are necessary.

Such a survey will yield information on the right-of-way (the length, direction of movement, capacity, and design standards of roads and tracks), terminals (the location, throughput capacity, and holding capacity of public transport stations, modal interchanges, and parking stations), and vehicles (the number, passenger or goods capacity, comfort level, and various operating characteristics of both public and private vehicles).

Travel pattern surveys also provide needed information on land use activity and a transport system. They reveal the travelers, their destination, and the time, mode, route, and purpose of the trip. Transport system performance surveys measure performance characteristics, such as travel times, travel time variability, passenger waiting times, vehicle occupancies, and system safety. They disclose whether the transport system is handling efficiently the demands being placed on it.

All of these surveys are concerned with collecting data about the transportation system as it exists, but transportation planners are often also required to offer credible predictions about future demands on a transport system as a result of changes in the system or its operating characteristics. Such predictions utilize demographic and socioeconomic surveys within the overall transport survey framework. Personal and attitude surveys can provide useful information concerning how individuals react to actual or perceived changes in the system.

Transportation surveys provide transportation planners with data that include passenger and freight information on volume, origin, and destination flows; costs of travel; impacts of travel influences

on demand; and substitutes for travel. Sound data enable transportation planners not only to plan for the future effectively but also to solve problems and sound warnings. Good data from surveys can show how best to relieve congestion, improve supply-chain connectivity to make freight transportation more competitive, and help consumers and providers to use the transportation system more efficiently. Freight transportation volumes can indicate changes in the economy at an early stage.

National Household Travel Survey

Among the best known travel surveys is the National Household Travel Survey (NHTS), a survey conducted approximately every five to seven years under the auspices of the U.S. Department of Transportation and funded through the Bureau of Transportation Statistics and the Federal Highway Administration. Its purpose is to gather information on both long-distance and local travel by the American public. Department of Transportation officials use the data to evaluate and review current programs and policies, study mobility issues, and plan for the future. States and metropolitan planning organizations find the data helpful for similar purposes.

Others who find the data useful include academics, consultants, and government officials outside the Department of Transportation who are interested in such information as travel behavior at the individual and household level, the relationship between demographics and travel, and the public's perceptions of the transportation system.

Some of those who use the data are less directly related to transportation. Medical researchers base determinations of the crash exposure rates of drivers and passengers on NHTS data. Safety specialists use the data to study the accident risk of school-age children, particularly when they are traveling on their own by walking or biking. Social service agencies are interested in how low-income households currently meet their travel needs.

Technology and Changes

Transportation surveys evolve with changes in the greater culture. In the 1970s, face-to-face interviews of randomly selected households and mail surveys yielded to random digit dial phone surveys. Two decades later, computers were used for electronic data collection through computer-assisted telephone

interviews, personal interviews, and self-interviews. In the 21st century, the Global Positioning System (GPS) is common in automobiles, cell phones have largely replaced landlines, market research regularly mines the Internet, and a variety of social media have transformed communication. Each of these technological advances has affected transportation surveys.

Transportation researchers, who suspected travel diarists often underreported their travel, have wished for a reliable means of quantifying data collected in this manner. Passive location data collection technologies, particularly GPS, can collect precise data on location, position, and speed. GPS-collected data first formed part of a major household travel survey in Austin, Texas, in 1997. Similar surveys have since been conducted numerous times, and transportation researchers believe GPS-only household travel surveys are a likely direction for future household travel surveys such as the national survey.

With costs of transportation surveys rising and funding shrinking, social media offer an appealing new means of conducting surveys. The top social media sites offer a broad sample of respondents; 56 percent of Americans have a social networking profile. Facebook, still the largest of an ever-growing number of social media sites, boasted 1.15 billion active users as of September 2013, and Facebook profiles typically include general demographic, educational, and geographic information, all of which can be useful in transportation surveys.

Internet-based surveys also offer the possibility of enhancement with images and audio, and the response rate for Internet-based surveys has been shown to be more than 10 percent higher than that of telephone surveys. These attractions are offset by the fact that social media users do not reflect the demographics of the United States. More users are female and urban, and young adults ages 18 to 29 are disproportionately represented.

Although 2013 statistics suggest greater ethnic, racial, and economic diversity among social media users, Internet access from home is still heavily skewed, with 76.2 percent of non-Hispanic whites and 82 percent Asians having access, compared to 58.3 percent Hispanics and 56.9 percent African Americans. The poor and the elderly are also less likely to have Internet access. Nevertheless, Web transportation surveys will likely be used with increasing frequency in the future, perhaps in conjunction with e-mail or traditional telephone-based

interviews, to add to information data collected from travelers.

Travel by Households

One of the prime motivations transportation professionals have for moving away from a traditional four-step travel demand model toward more advanced models has been to capture the interrelationships in travel among family and/or household members. The travel behavior of one household member can influence the travel behavior of other members in a variety of ways: trip generation may be impacted either positively or negatively, joint travel may be scheduled (and this desire to travel together may impact trip scheduling), and mode choice may be impacted in several directions.

While tour-based models do assert consistency in mode choice between half-tours (a significant improvement over trip-based models), they are not able to link travel behavior across individuals, which has led academic researchers and, increasingly, planners at planning agencies in larger metropolitan

areas, particularly in the United States, to research and implement activity-based models.

Household Impacts on Trip Generation

Household members can influence each other's travel behavior for mandatory travel, such as work or school tours, as well as non-mandatory tours. One common pattern is that when a child, particularly a young child, is home all day (does not travel to school), then an adult generally forgoes all other work and nonwork travel for that day.

When a worker and a nonworking adult are in the same household and one must care for an at-home child, the nonworker is by far the more likely to provide care. It should not come as a surprise that gender plays a role here, with adult females more likely to take care of children, even in the case when both household heads are full-time workers. In nontraditional households where retired adults are living with working adults, the senior household members often will fill in for a worker if a child is sick.

Another important observation is that certain needs (that must be satisfied by travel) are generated at the household level, but can then be allocated to a specific household member. This is most commonly seen in the case of shopping for groceries. Once this need has been satisfied, the maintenance travel of the remaining household members decreases. Larger households generate more travel than smaller households, all else being equal, but they often make fewer maintenance tours (or maintenance stops) on a per-person basis, though this does not necessarily hold true for discretionary travel.

Indeed, once one household member makes a discretionary tour, such as a social/recreation tour or an eating-out tour in the evening (as opposed to an at-work lunch activity), this may increase the likelihood of other household members also participating in a discretionary tour, precisely because this activity is often a shared one (that is, it is a type of joint tour). Seniors are observed participating in household joint travel, but at a lower rate relative to working adults and children.

When university students are living at home, they typically have the least interrelated travel of any of the person types, infrequently participating in household joint travel. University students are also the least likely to stay home to care for a sick child in the household. At the same time, they tend

The questions studied in travel behavior are broad and are very much related to activities of the typical household. Households with children are more likely to have parents who drive their children to school or to a day care center. For working parents, children are often dropped on the way to work, but the return trip may be more of a challenge since school hours typically end several hours before working parents are available to pick them up.

to have the lowest claim on household vehicles, so their interaction with other household members and their travel arrangements is quite low.

Impacts on Joint Travel and Trip Scheduling

Household members can make a variety of types of joint travel arrangements: joint travel where the activity and tour characteristics of the entire tour are shared by two or more household members, or partially joint travel. Typical examples of this include tours where household members share the inbound or outbound half-tour, but then the other half-tour is made independently with a different mode and/or different time-of-day characteristics, or escorting behavior where only some of the household members participate in the main activity and the other member(s) are simply there to provide transportation.

Joint travel behavior is actually quite prevalent, but only for nonwork travel. It is comparatively rare for two household members to have identical work

tours, as opposed to a situation where members coordinate travel but with different destinations or one member drops another member at a rail station, for example.

Joint travel between household members is being introduced to activity-based models in a gradual fashion with the focus on fully joint tours for non-mandatory trips, particularly shopping and social/recreation trips. The most complex intra-household behaviors being modeled involve escorting school children to school, which may involve coordination of two (or more) mandatory tours, given that multiple children may be being escorted.

In North America, parents are increasingly driving children to school (or to day care services). If the parent is a nonworker, this is typically an escorting tour, where the primary purpose is to deliver the child (or children) to school. However, for working parents, the child is often dropped off on the way to work. This requires coordination on the outbound leg and more significant adjustment on the inbound

leg, as school days frequently end several hours before working parents are available for pickup.

Families with younger children may turn to day-care services to bridge this gap, though this does not eliminate the need for coordinating household travel patterns at some level, given the penalties incurred if children are picked up after the agreed time. Households have come up with a number of coping strategies, including having children return from school on their own, having children participate in after-school care or after-school activities, having one working adult choose part-time work over full-time work, or having a different household member (with staggered hours) pick up the children on the return leg.

In some cases, households even cope by coordinating between households through multi-household coordination or carpooling, though in some ways this multiplies the difficulties inherent in coordination. Just as in the case of staying home to care for a sick child, if there is any escorting of children to school, it typically falls to female adults to engage in this escorting, though there are certainly exceptions to this pattern.

Coordination between household members is particularly important if escorting children to school is an activity the household engages in, but it is just as important if other joint travel is to take place. In order to understand (and predict) this behavior, time scheduling models take on considerable importance, well beyond the time-of-day factoring found in more trip-based travel-demand models. Some researchers have investigated not only scheduling but rescheduling models in order to find out how household members are able to coordinate their activities in order to fulfill their desired joint travel.

Household Impacts on Mode Choice

Mode choice, while often viewed as an individual decision, is impacted in a number of ways by the other household members. In the first place, car ownership is heavily influenced by household size and composition. Larger households and particularly households with two or more children are more likely to possess one or more cars.

Workers in households and household auto ownership are strongly positively correlated. Car ownership in and of itself tends to increase the use of car modes, but there is an important

caveat, which is only gradually being introduced into activity-based models, and that is the matter of car allocation. If there are fewer cars than licensed drivers in the household, then a car may not be available to everyone who wishes to use it to complete a tour. At the same time, it is clear from observations that many households do work out car sharing arrangements and rearranging of schedules to allow for dropping off and picking up of children and adults who lack a car (or prefer not to drive for a variety of reasons).

The allocation of vehicles within the household is another area for further research. In certain households, there is clear competition over the vehicles between the working household head with the longest work commute and the household adult (working or not) with the most child escorting duties. At the same time, it should be emphasized that this is a relatively rare situation in North America, where most households (at least those not living in the urban core) possess sufficient vehicles to avoid significant conflict over vehicles. Nonetheless, when vehicle type, age, and fuel efficiency are considered, there may still be competition over which vehicle is being used for which travel purposes.

Without understanding (and accounting for) these household dynamics, it would be hard to explain (and model) why so many school trips, in North America at any rate, are made via a shared-drive mode. Explicit consideration of joint travel also gives a much better understanding of why fully joint travel behavior is so commonly made as a shared drive tour. Joint travel tours are commonly made by driving and to a lesser extent by walking, whereas joint travel made by transit is infrequent. Without considering and modeling these tours as joint tours, to say nothing of modeling tours rather than separate trips, the shared nature of travel by household members cannot be captured.

Understanding of Household Travel

At minimum, understanding what portion of travel is individual based and what is household based will give researchers and planners a fuller understanding of the trade-offs already made by travelers. This may lead to different policies, such as a greater focus on increasing intra-household joint travel rather than inter-household carpooling.

When models can reveal that certain seemingly independent auto trips may actually be partially

joint travel involving pickup and drop-off of other household members, it becomes more apparent that these drivers may be considerably harder to switch to other modes than conventional models would indicate, particularly four-step trip-based models that have no linkages across travel behavior throughout the day. The trade-off is that attempting to represent more fine-grained behavioral realism requires increased complexity in travel demand models.

Travel by Mode

The analysis of transport mode use is essential to understand and/or forecast travel behavior, and therefore to respond to planning needs. Given the strong economic, social, and environmental stakes related to transport mode use, especially car use, a considerable number of empirical or theoretical works can be found in the last decades.

Various transport mode segmentations are available that depend on several dimensions. Distance consideration impacts the transport mode choice; for example, air transport is not relevant for urban

areas, or the option of walking for longer distances, except as a feeder mode.

Distinction between motorized and nonmotorized modes is significant when environment concern is important. Public versus private mode is also generally taken into account. But, available transport modes evolve, with new modes (for example, rent services like self-service bicycle, car sharing, and motorbike taxis) that contribute to reducing the frontier between private and public use.

Finally, more concern is being given to intermodality (that is, combination of several transport modes within the same trip) and multimodality (that is, use of different transport modes for travel over the course of the day or the week). This article first presents car use and the need to reduce its usage and then focuses on the main determinants of transport mode use.

Can We Reduce Car Domination?

Throughout the 20th century, the car has expanded its share against all other modes in nearly all market segments in most Organisation for Economic Co-operation and Development (OECD) countries. In OECD countries, individuals without car access are a minority, although they represent an increasing concern because social inclusion and equity—which can be negatively impacted by limited mobility—are receiving more and more attention in transport planning.

However, car domination is not universally true. In sub-Saharan African cities, only a minority of citizens (the richest 10 percent) regularly use a car for their daily mobility. In some developing countries, various forms of formal and informal public transport or individual modes (for example, bicycles, motorized two-wheelers, or walking) still have higher modal share than private cars. Nevertheless, in countries with high economic growth such as China, similar trends in car use growth, as in OECD nations during the 20th century can be observed.

With varying degrees of intensity, all industrialized countries have put car use reduction on their political agenda. This evolution meets various objectives. First, environmental concerns (greenhouse gas emissions and other pollution) demand restraint of the most polluting modes, such as private car.

Traffic congestion also represents an important economic loss, and most experts agree that it can no longer be mitigated by infrastructure

In India, walking, pushing, or towing with or without the assistance of an animal is still an important mode of transportation in most urban areas. To further improve conditions for pedestrians, Mumbai has commenced the construction of more than 50 skywalks, as part of the Mumbai Skywalk project.

development. Equity and social inclusion require the development of alternatives for those who do not have access to car.

This has explained the development of public transport to some extent. Especially in European countries, development of public transport is favored not only for social equity but also for economic and environmental reasons.

More recently, nonmotorized transport modes have received more attention. Of course, they respond to environmental concerns and they also represent an economic solution both for individuals and for transport authorities. They also respond to the growing concern for transport solutions to health-related issues. Walking and cycling, used as a sole mode of transport on whole trips or to access public transport stations, are highly recommended as a way for city

dwellers to perform daily physical exercise in order to curb obesity and health problems.

All these developments in transport are increasingly interacting with built-environment concerns, which are receiving growing interest from researchers and practitioners. Car reduction targets are most commonly defined in urban planning, but success in meeting these requirements requires understanding the reasons for car use and the mechanisms that might result in switching to other transport modes.

Travel Mode Determinants

A considerable amount of work focuses on mode-choice understanding. Most determinants fall into four broad categories: The first, trip characteristics, includes purpose, origin-destination (OD), distance, and monetary cost, which impact mode use. In industrialized countries, modal share of walking is mainly restricted to trips of less than one mile. Cycling usage is strongly decreasing for distances of more than 3 miles, except in certain countries such as the Netherlands and Denmark. Monetary factors (gasoline, car parking, etc.) can strongly impact car use, especially in most central areas of European cities. The cost of public transport can hinder the mobility of low-income individuals in developing countries who have to “choose” between public transport and walking, as well as poorer people in developed countries, who are less likely to walk and have few public transport options. In early research, only the main transport mode was considered, but now, intermodal transfers are increasingly taken into account.

The second category, transport supply, also impacts modal choice. Public transport use is greater in large cities, especially in the most central area where public transport supply is the highest and car performance the lowest. Supply also has an influence on nonmotorized mode use.

Even if it is probably not the only reason, cycling is at its highest in the Netherlands and in Denmark, where cycling lane supply is also more developed. Supply level is important, but perceived quality of service also influences choice. Comfort, information, accessibility (especially for people with disabilities), and even image play important roles in travel mode choice. The built environment and urban form have also a direct impact on transport mode use. Low density generally favors car use, whereas high density encourages public transport use. The mix of urban land use functions (for example,

housing, job, shopping, etc.) and high integration between transport and land use allow the greater development of cycling and walking, as is seen in transit-oriented development.

Individual and household characteristics strongly impact mode usage. Gender, age, generation, activity status, and income are generally associated with differences in mode choice. Stage in life cycle appears also important; when individuals are moving from one stage to another appears to be the best period to encourage modal shift. These “objective” factors need to be combined with social perceptions and cultural and attitudinal factors associated with travel modes, because it appears that they could be strong forces to motivate behavioral change, as envisaged in travel demand management actions, for instance.

Conclusion

Considerable knowledge has been accumulated on determinants of travel mode. This knowledge is more and more used in order to propose new transport policies emphasizing the need to increase the use of more sustainable, safer, and more healthful transport modes. More local measures are also developing, such as company mobility plans or travel demand management programs. The need remains, however, to develop research to better understand the way mode use can change through transport policy, land use and built environment planning, or more personal changes. Also needed is longer-term planning, which implies continuing to develop models of interaction between transport and land use.

Travel by Persons

The mode of transport used by a person is dependent upon a complex set of often interdependent variables. Understanding the reasons behind particular choices of transport is important in providing an evidence base for the development of effective policies, transport strategies, and plans that will change current patterns of travel behavior in favor of more sustainable mobility.

According to the European Environment Agency (EEA), the impacts of transport are vast and significant. Transport in Europe accounts for over one-third of all final energy consumption and for one-fifth of greenhouse gas emissions. In addition, transport affects noise levels, urban air pollution, and concentrations of particulate matter, particularly in urban environments, and it often requires damage to the landscape for the purpose of roadways, runways, navigation, and the associated supporting infrastructure.

Other direct and indirect consequences of transport networks include the destruction of natural habitats (and sometimes whole ecosystems) in the new construction or improvements to existing road, rail, waterway, bike, and pedestrian routes. Detrimental effects on human health (for example, increased respiratory problems) and a reduction in overall plant life and crop yields can also result from high atmospheric pollution levels, to which transportation in its variety of forms contributes.

Nevertheless, travel is an integral component of everyday life. Many activities people want to engage in are separated by space, which requires people to travel. Traveling, and transport in its many forms, enables individuals to meet their needs and provides access to other people, locations, services, and opportunities.

Trips are made for a variety of reasons, including commuting to a place of work, sightseeing and tourism, for leisure purposes, and so-called maintenance trips, such as shopping, accessing health care facilities, and taking children to school. The

transportation choices people make in traveling are based upon their options, constraints, habits, and opportunities.

The amount traveled by individuals is increasing across the globe as modes of transport become ever more accessible. In the United Kingdom (UK), for example, the distances traveled each year by individuals has increased fourfold since the 1950s and 1960s. During the same period, total passenger miles traveled by car increased by over 900 percent, while rail has increased by 26 percent. Similarly, in the United States distances traveled rose by 155 percent between 1970 and 2010.

All other modes have declined, however, including bus travel (by 50 percent), cycling (by 83 percent), and walking. Little research work has been undertaken on travel behavior and modal choice in developing countries, where in many countries vehicle ownership is significantly lower and the need to travel may be offset by constraints in the individual's ability to travel.

In Europe, trips by car (as a driver or passenger) accounted for 64 percent of all trips made and 78 percent of distance traveled in 2010. The arguments for car use, including convenience, speed, comfort, and individual freedom, mean that in most industrialized countries the automobile is the most widely used mode of individual transport.

Travel Behavior

Understanding individual travel behavior, its driving forces, and its influences is important in order to be capable of changing behaviors. Behavioral change is necessary in the transport mode choices of individuals because of the environmental and human health implications of most people's current patterns of mobility.

To understand the factors that trigger certain transport mode choices, transport behavior research has emerged as a discipline. The purpose of transport behavior research is to identify the reasons and stimuli for transport choices through the gathering of data on aspects of an individual's or group's (often referred to as a "segmentation") travel behavior. This knowledge is then used to develop effective transport strategies and sustainable transport systems, which will create more sustainable patterns of travel by persons, or sustainable mobility.

In general, what is clear through transport behavior research is that the choice of mode of

transport depends upon interactions among individual factors such as attitudes and opportunities, and the accessibility of places and activities (that is, the distribution in space of the individuals and the infrastructure accessible to them). Research has concentrated until recently on the spatial-temporal context of transport mode and choice.

The attributes of travel behavior can be classified into four different groups: a land use component (locations and characteristics of opportunities and of demand), a transport component (location and characteristics of infrastructure for passenger and freight travel), a temporal component (opening hours of shops, available time for activities, etc.), and an individual component (for example, income, gender, educational level, mobility resources, and vehicle ownership).

The customary attributes identified and studied in travel behavior research include the spatial and urban structure, the availability and service of a transport system, economic factors, political and planning factors, and social and demographic factors. The most important sociodemographic variables influencing the mode of transport used by individuals include age, household composition, income, gender, and car ownership.

Cost is a primary driver of choice of transport mode, as is household composition and income. Key stages within the household life cycle that impact travel behaviors include gaining employment, having children, and retirement. Households with children have distinct travel behavior characteristics, including being highly dependent on cars as the primary source of travel mode.

The process of establishing habits, which is recognized as an influence of travel mode choice and mobility decisions taken by individuals, can be unfavorable to attempts at behavior change. On a day-to-day basis, people's travel mode choice is often habitual and not usually preceded by the deliberation of alternatives.

When a person's response to travel mode choice is a product of habit, it is known as automation. This automation or habitual character of individual travel behavior is the main reason for the common resistance of individual travel behavior to influencing measures; the automation intensifies the individual's focus on one chosen means of transport and reduces the perception of travel alternatives.

Psychological Factors

More recently, psychological factors, including perceptions, identity, social norms, and habit, are being used to understand travel mode choice. Likewise, psychosocial variables have been found to influence travel behavior.

One study looked into the significance of the car as a means of providing protection, autonomy, and prestige, as compared with public transport. Participants considered that they had greater protection from “undesirable” people with the use of automobiles and that private vehicles also provided autonomy, convenience, and greater access to a wider range of destinations than public transport.

Socially desirable attributes, such as competence, skill, and masculinity, were also perceived to be derived from car ownership. People who did not own cars were seen as eccentrics because of their nonconformity with what is perceived as the social norm. The recognition of the need to capture psychological factors in transport behavior research marks a departure from the theory of planned behavior, which is grounded in the belief that choice of travel mode is predominantly a reasoned decision related to attitudes, social norms, and perceived barriers to other forms of travel behavior.

Sociodemographic Segmentation

The *a priori* approach has been used almost exclusively in travel behavior research. With this approach, groups are selected from a population in advance, with the selection based upon known characteristics, usually such socioeconomic characteristics as income or gender. These groups of like-characteristics are known as segments. Sociodemographic segmentation is considered by some to be limited in what it can achieve because it does not take account of the more complex, statistically derived clusters of characteristics that are considered more representative of the population.

It has been argued that different people must be treated in different ways because they are motivated by different factors and are affected in different ways by policy. Thus, the customary segmentation based upon rationalist theoretical underpinning does not provide the framework upon which to understand the reasons for travel choice made by individuals.

One of the most dominant influences of travel choice for individuals is the built environment. This

holds true for industrialized and industrializing countries. This is widely recognized and has been demonstrated through a number of studies in different countries and different geographical areas. What is common to all, however, is that land use patterns influence travel behavior and the decision whether to use public transport, share a car, or drive alone.

The Australian Bureau of Statistics has identified that public transport use is considerably higher in capital cities than in other parts of Australia. This is a result of the more extensive and frequent public transport infrastructure available and accessible. These studies also show that those located in more rural areas and on urban fringes have the least sustainable travel behaviors, which is likely to pose greater challenges to policy makers in bringing forward sustainable travel systems.

Researchers in India identified that in densely populated areas of central Chennai, people were more likely to use nonmotorized modes of travel (walk or bicycle) than those on the periphery. They found that accessibility to transport modes is linked to the location of employment opportunities.

Higher residential density has been found to reduce solo-commuting (driver-only car commuting). Similarly, researchers have found that U.S. land use patterns reinforce vehicle dependence when they have compared suburban sprawl to areas with tighter urban planning and design controls in European countries. This research has led to more compact and higher-density urban forms, which leads, generally, to greater use of public transport or walking or cycling.

Another researcher concluded that location played a large part in the sustainability of travel behavior, with those living outside urban hubs and in rural areas using on average three times more fuel than those more centrally based in urban areas.

The environmental impact of the spatial influence of travel choice is greater for households in low-density and rural areas than those in very high-density areas, which produce approximately half the carbon dioxide emissions of their rural counterparts. Furthermore, when comparing the carbon footprint of automobile travel by individual households in rural and urban areas, more miles are traveled by rural households—approximately 8,000 vehicle miles traveled (VMT) annually compared to 4,000 VMT for those in urban areas.

For those in rural areas, fuel efficiency is dependent upon the nature, age, and size of the vehicle used. More fuel-efficient vehicles, then, can offset some of the increased carbon emissions resulting from the spatial dimension of travel and accessibility to transport alternatives, but this is dependent upon largely sociodemographic factors, particularly higher income.

In the UK, one of the Department for Transport's key environmental impact indicators for travel is the proportion of urban trips under five miles that people take either by walking, cycling, or public transport. However, it must be remembered in travel behavior research that people's ability to use alternative means of transport, whether for short or longer journeys, may be constrained by health, the lack of provision of facilities, or the temporal nature of that provision.

Qualitative Methods

The traditional approach to understanding travel by persons was to use quantitative methods of research. While this type of study methodological technique provides useful numeric data on those traveling, clarifying the who, what, where, and how, quantitative data are not predisposed to uncover the most critical question for transport policy development—the reasons for the mode of transport chosen. This is where qualitative methods have an increasingly important role to play in transport behavior research.

Qualitative methods facilitate understanding and provide insight into the complexities of travel behavior. Methods include focus groups, interviews, participant-observation techniques, and travel diaries (in which subjects capture details of all travel modes used within a particular time period).

These methods complement rather than annul quantitative approaches. In order to ensure quality of the data collected by way of qualitative research techniques, the techniques must be used with scientific rigor and grounded in theoretical frameworks. All empirical research into travel behavior and choice should be undertaken, as with any other research, to ensure high ethical standards, information, and protection for participants.

Conclusion

Travel behavior research is an evolving discipline. It grapples with highly complex issues that collectively determine an individual's choice of travel mode. Research in this field has recognized the

limitations of segmented research techniques and the greater intricacies of travel behavior; this will improve the evidence base for the creation of sustainable travel behavior.

Travel by individuals is mainly undertaken by automobile, but this depends upon a host of variables, including infrastructural, socioeconomic, demographic, and psychological factors. Factors affecting the embrace of alternate transport modes include a lack of awareness. This issue can be easily overcome with awareness campaigns and other soft transport policy initiatives.

Travel Choice

Travel choice refers to understanding how people make choices regarding their travel plans. This includes how much they travel, for what purposes, where, at what times, and by which mode. Another aspect asks how people make such decisions for the transport of commodities.

As a field, travel choice deals with theoretical constructs, behavioral assumptions, and methodologies for the analysis, representation, and inference of the way travelers behave and the interrelationships of this behavior with their activities, land use, and the transportation system. The understanding of these various aspects requires an interdisciplinary inquiry, engaging geography, engineering, statistics, urban and regional studies, economy, psychology, and sociology.

While the basic travel technology, the car, has changed relatively slowly, many other factors induce significant changes in travel behavior. In modern life, there is more leisure time and more engagement in nonwork out-of-home activities.

Work hours have become more flexible and more women are in the labor market. Information and communication technologies provide travelers with better information and enable substitute travel for all purposes. Work trips are no longer predominant, because there are more trips for shopping, social, and leisure purposes; trip chaining is more frequent; and traffic peaks are smoother.

These changes made household travel patterns more complicated by significantly increasing the number of alternative activity and travel patterns available to households. The relaxation of some constraints, such as the need to commute at fixed hours, provides more freedom and more alternatives, thus making the analysis of travel choices more complicated. At the same time, these changes significantly increase congestion and air pollution from motor vehicles, raising as a result the need to develop new objectives of policy and planning toward sustainable transportation.

The growing complexity in travel patterns and the need to estimate changes in travel choice in response to new policies have called for a better understanding of travel behavior. This includes issues such as how travel behavior is affected by new information and communication technologies, how land use and growth management affect travel behavior, and how travelers respond to auto restraint policies.

Understanding such effects is essential for a better design of new policies. In this regard, travel behavior lies at the core of procedures for the analysis and evaluation of transportation-related measures aimed at improving urban mobility, environmental quality, and a wide variety of social objectives.

Historically, the field has changed over time parallel to changes in transportation systems, planning goals, and travel behavior. In the 1960s, the development of the American interstate highway system led to the development of an operational macro-level system of models providing planners and engineers with travel demand forecasting tools.

This system, also known as the four-step process, relies on statistical tools and enables the forecast of various travel choice elements in an aggregate manner given the land use structure and socioeconomic characteristics of the population. In the late 1960s, additional emphasis was given to economic approaches motivated by the need to better understand travel behavior and to derive a value of behavioral travel time saving for cost-benefit analysis.

In the 1970s, the economic theory of the allocation and valuation of time developed toward an econometric approach providing a framework for modeling travel behavior. This approach was based on random utility modeling (RUM).

Thereafter, a growing interest in and the need to better understand the motives for travel behavior prompted the involvement of psychology, among other social sciences. Some of these studies questioned whether the RUM paradigm could accurately represent the set of decisions travelers use. That led to the development of the rules-based paradigm as an alternative method. In both approaches there is a move toward an activity-based framework in which there is an effort to understand travel behavior as derived from activity participation and time-use behavior.

Qualitative data on travel behavior, collected by various types of travel surveys, is an essential element to all these efforts. The most common surveys are travel habit surveys, where respondents are asked to report details about all their trips within a given time period, usually at least 24 hours. Stated-preference data, in which people are asked to indicate their choice among various alternatives under some hypothetical scenarios, are used to estimate travel choices for new modes or policies that do not currently exist.

State and regional transportation planning organizations use travel demand models to forecast people's travel choices and their impact on the transportation systems. The four-step model mentioned above is still the most common model used for this purpose. This is mostly an aggregate model where

Travel choices can sometimes be made for social reasons as well as economic reasons. An important role of optional modes of transportation is ensuring that all members of society are able to travel, not just those with a driver's license and access to an automobile. Rail travel, for instance, offers transport at an economy of scale not available through private transport.

the four steps represent the main travel choices people make: how much to travel (trip generation), where to travel or how these trips are distributed in space (trip distribution), which modes are they using (mode choice), and which routes, either high-way routes or public transportation routes, they are using (traffic or public transport assignment). A fifth step—time of day—is usually added to represent the choice of time of day in which these trips are conducted.

Policy makers are most interested in the mode choice people make, trying to design policies to encourage people to shift from automobile modes to public transport and nonmotorized modes. Accordingly, even within this aggregate framework, many of the mode choice models are estimated as disaggregate models to better understand individual mode choice.

Some transportation planning organizations have already developed fully disaggregate travel demand choice models based on the activity-based paradigm that can better analyze travel behavior and response to policies.

Travel Demand

Travel demand generally refers to the movement of goods and people, that is, activities people do over space. Travel demand can be defined from many different perspectives. Some quantifiable measures of travel demand are the following:

- *Frequency of trips*: How many trips does one person make?
- *Trip length*: How far is the trip?
- *Mode*: What transportation mode(s) does the person use? Walking, bicycling, car or transit, or a combination of all?
- *Purpose*: why does the person want to make the trip? Why not stay at home and telecommute?
- *Sequence*: What is the pattern of trips? Is this a chained trip?
- *Path*: Which route does the person choose? Who accompanies whom?
- *Departure time*: When is the trip made? Is the departure time flexible?
- *Duration*: How long will the trip last?
- *Cost*: How much money or equivalent time spent is on the trip?

Factors Influencing Travel Demand

Individuals' travel demand can be directly influenced by many factors, with demographic trends, economic activities, land use patterns, and transportation facilities being among the most influential. Studies on the impacts of land use on travel demand can be traced to the 1970s. Researchers P. G. Newman and J. R. Kenworthy compared population density and gasoline consumption in several metropolitan areas and concluded that gasoline consumption decreased with higher density. The study's results were taken up by proponents of the new urbanism movement and neotraditional designs in the 1990s who argued for more intense development patterns.

Later studies have analyzed the relationship between the built environment and travel demand looking at different aspects of travel demand, including vehicle miles traveled (VMT), travel mode, and trip frequency. These studies also found that households in higher density neighborhoods tend to own fewer vehicles and that households owning fewer cars tend to use transit more and generate fewer VMT.

Transportation facilities are expected to play an influential role: factors related to transportation infrastructure include roadway conditions (such as scale, network connectivity, operational strategies and pavement conditions), walking and cycling conditions, and transit service. The combination of transit service with other strategies, such as transit-oriented development (TOD), has been found to cause noticeable changes in travel mode (more reliance on transit) and length (shorter trips).

Traditional studies mainly focus on population density and demographic characteristics without placing them into a spatial context. However, the centeredness and distribution pattern is often the real determining factor of residents' travel demand. Compared to uniformly distributed populations, clustered populations tend to have shorter and less frequent trips. Recent studies have resorted to spatial statistics to quantify the spatial patterns of demographics.

A major part of travel demand comes from economic activities such as working, shopping, and entertaining. The pattern of economic activities is often evaluated by an accessibility index, which captures the interaction between the location of interest and the economic entities in its neighboring areas. For example, the employment accessibility index, often calculated as the weighted (by inverse of distance) summation of surrounding employment is normally found to be negatively correlated with commuting trip distance.

A rational person will choose the way of travel that maximizes his or her own utility. People have different utility functions and preferences, which affect their travel decisions, leading to observable heterogeneity in travel demand. Aggregate analysis often neglects such heterogeneity in travel demand forecasting, leading to results that indicate insensitivity to policy change. Recognizing this problem, more sophisticated travel demand analysis today often relies on disaggregate approaches.

Public policy can have great influence on travel demand. For example, some cities have experimented with closing certain areas to traffic or charging a fee for entrance, or implementing “odd-even” traffic restrictions, in order to control travel demand.

Estimation Methods

There are generally four types of approaches used for estimating travel demand, with increasing data requirements and estimation accuracy: growth factor, land use trip rates, cross-classification, and regression models.

Growth factor methods assume uniform growth rates relative to the base year. The number of future trips equals the product of the growth factor and the base year travel demand, where the growth factor is often determined by the demographic features in the base year and future year. Growth factor models are easy to understand and relatively reliable for short-term forecasting. However, they require travel demand data for the base year and do not account for changes in land use or any other key facilities.

As the name suggests, the land use trip rates method estimates travel demand based on trip rates generated by specific types of land use and the total amount of that land use type, indicated by variables such as total area of establishment. The Institution of Transportation Engineers (ITE) Trip Generation Manual provides complete guidelines on this method. The land use trip rates method is popularly used in traffic impact analysis for specific land development projects and long-term planning for small cities. This method is also easy to use and easy to interpret, with low data requirements. However, as this method does not incorporate any behavioral or social-economic information, its explanatory power is often low.

Cross-classification can be considered a more sophisticated version of the trip rates method, as it first determines trip rates as a function of socioeconomic attributes (often at household level). Typical socioeconomic variables used include household income, car ownership, and family structure. Cross classification is more flexible than trip rates in that it better accommodates heterogeneity. It does not rely on information about the zoning system and does not require any assumptions regarding dependent and independent variables.

However, this method requires much larger sample sizes to achieve reliable estimates. It does

not allow for extrapolation beyond the calibration data and there is no efficient way to identify the best variables.

The development of econometric models in the last several decades has enabled more sophisticated estimation of travel demand. Many types of models have been developed to address the different aspects of travel demand. For instance, linear models are often used to estimate total demand at the zonal level; count data models can be used to estimate travel frequency at the individual or household level; discrete choice models are used for estimating mode choice; hazard models can be used to estimate the duration of a trip. Depending on the data characteristics and the probability functions, different models can be derived.

Compared to the previous methods, regression models are more behaviorally consistent, statistically more rigorous, allow for selection of independent variables, and have better explanatory and predictive powers. The downside of regression models includes their high data requirements, the accuracy of model estimates, and the need for careful interpretation of results.

Travel Demand Forecasting

Federal law in the United States mandates that state and metropolitan planning organizations must develop transportation plans and programs to accommodate the mobility requirements of people and goods within their regional boundaries. Travel demand forecasting is an integral tool used to help transportation planning organizations and other key constituents in government and industry estimate future travel demand and assess the associated financial, social, and environmental impacts of various transportation scenarios.

The findings from the forecasting process are used to help establish transportation policies, facilitate transportation planning, and enable informed decisions pertaining to transportation infrastructure, usage, and impacts.

Conventional travel demand forecasting covers a broad array of considerations and activities that address various transportation types and systems, time frames, geographies, regulatory and policy issues, and needs of key stakeholder groups. Forecasting models typically follow a four-step process aimed at reasonably estimating travel volumes and implications associated with specific types of transportation infrastructure, such as roadways and bridges, rail lines, airports and water ports, occurring at a given period of time, such as during rush hour, weekends, or over the life span of the transport mechanism. Travel demand forecasting models may also incorporate specific considerations tied to air quality standards, land use patterns, safety issues, pricing options, commercial repercussions, and other factors.

The Forecasting Process

The base unit of measurement in traditional travel demand forecasting models is called the trip, defined as an individual or vehicle traveling from a point of origin to a point of destination without

making intermediate stops along the way. Each trip is further defined by the purpose behind the trip, such as work- or non-work-related travel, and is shaped in part by data availability, planning needs, and regional characteristics.

The first step in the travel demand forecasting process focuses on trip generation. Modeling at this stage seeks to estimate the number of trips of each type that start or terminate in each location based on the amount of activity in the area being analyzed, sometimes referred to as the traffic analysis zone. The trip type is generally broken down into three broad categories: vehicle trips; person trips by motorized means such as automobile and transit; or person trips by any means, which can include motorized as well as nonmotorized modes such as bicycling or walking.

Trip generation models also may account for household variables linked to trip-making behavior. These variables may include the number of household inhabitants overall, the number of workers within a household and their employment type, the total income level of a household, and the availability of and access to vehicles among members of the household.

The second step in travel demand forecasting addresses trip distribution, which seeks to quantify the volume of trips traveling between specific traffic analysis zones. In some cases, travel demand forecasting models may assess travel qualities and behaviors occurring outside the traffic analysis zone. The trip distribution step in the modeling process incorporates variables related to cost parameters associated with travel between zones. Trip distribution variables also consider the amount of trip-making activity in both the originating zone and the ultimate destination zone.

After trip distribution is modeled, forecasters focus on a step known as mode choice. This third step involves dividing the trip distribution results into trips categorized by travel mode. The mode definitions vary based on the types of transportation options available in traffic analysis zones and by the types of planning analyses needed.

The mode definitions are typically grouped into automobile modes, transit modes, and nonmotorized modes. Automobile modes are most often defined by occupancy levels of a vehicle, while transit modes encompass access and service types such as personal automobile, express bus, commuter rail,

and other transport options. Nonmotorized modes include walking and bike riding activities as part of the forecasting model.

The fourth and final stage of the traditional travel demand forecasting process is trip assignment, which includes distinct highway and transit assignment components. The highway assignment process maps vehicle trips from the origin-destination models created earlier in the forecasting process onto paths along the highway network to assess traffic volumes by time of day and vehicle type. Adding variables related to vehicle speed and expected travel times helps indicate levels of traffic congestion at various points along the network links. The transit assignment process maps trips from the prior transit trip models onto individual transit routes and links to provide data about specific transit line volumes and usage, such as station stops, boardings, and departures.

Sometimes a separate step known as time-of-day modeling is used as part of the travel demand forecasting process as a way to further differentiate daily trips into specific time periods, such as morning and late afternoon peak periods, midday, and evening off-peak periods. This supporting step may be applied at any time between the trip generation and trip assignment stages of the conventional travel demand forecasting process.

Emerging Approaches

Increasingly advanced approaches to modeling have emerged over the years as the expectations and requirements of travel demand forecasting have expanded to accommodate evolving regulatory and market-based needs. Among the newer techniques and parameters being utilized are activity-based models, dynamic traffic assignment models, and traffic simulation models.

Unlike the traditional travel demand forecasting process that views travel participation primarily as a trip, activity-based models consider travel to be a demand that is driven by the need to pursue activities. In essence, activity-based forecasting treats travel as a means to an end rather than conventional modeling that treats it as an end in itself. Underlying the activity-based approach is a desire to better understand the behavioral rationale behind individual decisions leading to participation in certain activities in specific places at particular times. Those factors serve as the basis for travel

needs and practices according to the activity-based theory. Among the factors considered in this type of forecasting model are the needs, preferences, and habits of individuals and groups; the cultural and social norms of the relevant community; and the travel service options available within the surrounding environment.

Activity-based modeling uses tours rather than trips as the basic unit to represent travel patterns. Tours are defined as chains of trips that start and end at the same location, like home or the office. Focusing on tours helps illuminate consistencies/inconsistencies as well as interdependencies within the behavioral attributes and travel activities comprising a single tour. In the traditional trip-based approach, each trip is considered to be independent from other trips, making it difficult to connect potentially important relationships within the modeling data.

The dynamic traffic assignment model aims to predict traffic flow conditions under various sociodemographic, land use, and service capacity circumstances. Traffic flow conditions result from the interactions between travel demand at an individual level and travel types and service capacity provided by the transportation system. In this model, activity-based travel patterns are put into traffic assignments based on specified levels of service and capacity. A repetitive feedback process is employed to ensure accurate consideration of dynamic supply and demand interactions tied to activity-based travel behaviors and consequential traffic flow conditions.

Most dynamic traffic assignment models are supported by a traffic simulation model that replicates the expected movement of traffic using defined network parameters linked with spatial pathway projections and travel time estimates. This approach offers forecasters the ability to address time-dependent traffic conditions across the traffic network with greater spatial accuracy than traditional traffic assignment models, thus enabling more accurate estimation of the effects of traffic controls and technologies. Similar forecasting models are available to support transit passenger simulations.

Depending on the distinct transportation issue under evaluation, the specific travel demand forecasting model utilized will vary in its underlying process and structure, in the parameters included for consideration, and in the scope and complexity of analysis. Regardless of the approach selected, the

intent of any travel demand forecasting effort is to create relevant models with accurate data that can be used to identify needs and inform transportation planning decisions.

Travel Destinations

Travel destination is one of the numerous areas of travel examined by travel researchers, and is often best understood in the context of other travel decisions, such as the mode of transport, the route choices, who accompanies the traveler, and the purpose of the trip itself.

In particular, travel destination is often looked at in the context of vacations and other recreational and social travel and why travelers make the choices they make. The better researchers understand these choices and decision-making mechanisms, the better they can forecast traffic and the economic and environmental impacts of travel, by creating more accurate transportation planning models and simulations. Such models depend on high-quality data sets, of course.

The Federal Highway Administration, in the U.S. Department of Transportation, administers the

National Household Travel Survey (preceded from 1969 to 1995 by the National Personal Transportation Survey) at irregular intervals (most recently 2001 and 2009) to collect information on Americans' travel choices, transport mode usage, and travel miles. However, in the area of examining destination choice and recreational travel, the data are not as useful as they are in looking at commuting behaviors and other matters more directly relevant to federal transportation policy. Travel diaries, on the other hand, can be very useful when researchers are able to interest enough participants in maintaining them.

Travel behavior and selection of destinations is widely hypothesized by researchers to be influenced by self-congruity: the congruity between a tourist's self-concept and the destination visitor image. This is as important as, and believed to influence, functional congruity, which is the congruity between the useful aspects (or "good points") about a travel destination and the tourist's ideal expectations of those aspects. The environment of the destination itself also affects the destination visitor image and the tourist's perception of the destination's good points.

Destination image is, of course, also key—the beliefs and awareness that an individual has about the destination, including knowledge, actual experiences, perceptions, and emotions. Destination image is informed by numerous factors, including indirect and direct experiences, the portrayal of a destination in pop culture, news coverage, encounters with people from the destination, and so on. Numerous studies since the 1970s have shown the ways that destination image influences tourist choices, and travel decision-making models have reflected this. C. Gunn's model of seven phases of the travel experience depends heavily on the importance of destination image:

1. The traveler creates mental images about vacation experiences based on various sources of information. This destination image is the organic image, based mainly on sources of information like social contacts, learning from school, pop culture depictions, and the news.
2. Those images are modified by further information specific to travel and tourist activities, such as those prepared

commercially for and by travel agents. In the model, this is called the induced image.

3. The traveler decides to take a trip to the destination.
4. The trip occurs.
5. The traveler has experiences at the destination.
6. The traveler returns home.
7. The traveler's mental images are modified in accordance with his experience.

The first, second, and last phases are states of destination image formation, the first two using secondary sources of information, and the last using firsthand experience.

Travel satisfaction depends in part on how the travel experience, the experience of the destination, compares to expectation, especially the value of expected positive experiences. Various researchers have suggested models for measuring destination image and satisfaction, based on rating a number of attributes according to a scale, and comparing the scores (some models weight the attributes) of the destination image with the destination experience.

For instance, P. L. Pearce's model proposed in 1982 uses 13 attributes on a six-point scale. J. L. Crompton's 1979 model uses 30 attributes on a seven-point scale. A. Phelps's 1986 model uses 32 attributes in a simple yes/no checklist. Other models that use unstructured open-ended questions to interrogate the traveler do not provide a methodology for generating a quantitative score.

Destination characteristics may be separated into categories like functional (the climate, the costs of expenses) versus psychological (the friendliness of the people encountered), or common (the hotel had HBO) versus unique (the hotel was *Star Wars*-themed). Typical characteristics discussed in surveys interrogating destination image include scenery and natural attractions, costs and fairness of costs, climate, tourist activities and attractions, nightlife, sports facilities or activities, national parks and wilderness activities, local infrastructure and transportation, architecture, historic sites and museums, beaches, shopping, special accommodations, cities, fairs, exhibits, festivals, tours, crowdedness, cleanliness, perceptions of safety, economic development and affluence, urbanization, commercialization, political stability, hospitality and

Visitors to Las Vegas, Nevada, take a gondola ride under an artificial sky in an indoor shopping mall at the Venetian Hotel in 2011. Studies have found that in selecting destinations, travelers are influenced by combinations of novelty-seeking and familiar-seeking, and cultural proximity has an influence on satisfaction.

friendliness, differences in customs and culture, differences in cuisine, restfulness, atmosphere (which can be described qualitatively as well as rated quantitatively), opportunity for adventure, opportunity for learning, family oriented versus adult oriented, and fame or reputation.

At least one recent study has suggested that "cultural proximity" is a factor in destination image as well, with the destination image of a given destination improving if the tourist feels it represents a culture similar to his or her own. Some studies have attempted to have tourists describe destinations in terms of personality traits, as has been done with brand personality studies, but only a handful of 21st-century studies have demonstrated tourists' ability to do so. Often it seems to be easier for

tourists to do so when the destination is one with extensive exposure in pop culture and the popular imagination.

Researchers Ahmet Usakli and Seyhmus Baloglu's 2011 study on self-congruity, for instance, found that in a sampling of 368 visitors to Las Vegas, a consensus developed that Las Vegas can be described as "vibrant, sophisticated, competent, contemporary, and sincere," at least some of which invokes personality descriptors not often applied to places.

Self-concept in general is important in consumer choices, and self-congruity theory was originally proposed in reference to brand perceptions and satisfaction but applied to tourism in 1992. The impact of cultural proximity on travel satisfaction is an example of the ways self-concept impinges on travel experience. To oversimplify somewhat, people's experience of travel is influenced by what they believe that travel says about them and how they feel about what it says about them.

As with destination image, self-congruity can be considered in both functional and psychological or symbolic categories. A number of studies have found that in selecting destinations, potential travelers—especially if cost is not a concern, such as in hypothetical "dream vacation" surveys—select destinations that externalize their self-image. The congruity of self and destination has been found to have a determining impact on whether the traveler makes a return trip, but interestingly, it has no perceptible impact on whether the traveler recommends the destination to others.

Another motive for selecting a destination is what behavior psychologists call novelty seeking. Novelty seeking is part of the complex equation behind the traveler's decision-making process, which weighs risks and rewards. While any new experience carries a risk of unpleasantness, mediocrity, or boredom, the idea of novelty seeking as a motive assigns a value to newness itself: independent of the value of the satisfaction and enjoyment the experience may eventually bring, the fact that it is new gives it a perceived value in the decision-making stage. People are also motivated by familiar-seeking, though—the desire to have experiences that comfort by being similar to experiences we have previously enjoyed.

The combination of novelty seeking and familiar seeking as motives, with cultural proximity as an influence on satisfaction, suggests destinations like

near neighbors—Mexico, for instance, for Americans, or simply other American cities with especially overt personalities like Las Vegas, New York, and New Orleans. Of course, the extent to which an individual is motivated by novelty seeking or familiar seeking varies greatly from person to person, as does one's openness to new experiences and the unknown.

Travel Diaries

Travel diaries have been adopted relatively recently as a considerably more advanced method to collect trip information over a 24-hour period. In travel diary surveys, randomly selected participants are asked to personally record information about each trip that they make during a one-day to one-week period.

Participants of travel-diary surveys record trip origin, destination, time, mode, and other characteristics into their travel diaries. The earliest travel diary studies used paper-and-pencil techniques, which resulted in errors resulting from omissions of trips or trip elements, language issues, illegible handwriting, and key entry errors. The paper-and-pencil method has been replaced with computer-assisted telephone-interviews, which use specialized software to call survey respondents.

Travel diaries have taken three main forms: trip based, place based, and activity based. In the trip-based diary, respondents are asked to report each origin-to-destination movement that they undertook over a daily period, without explicitly requiring the respondent to report trips in chronological order.

Activity-based diaries ask respondents to list the activities they did and follow up by asking how the respondent traveled to the place where this activity occurred. In this survey type, the recall of activity participation is requested in chronological order for the entire diary period.

The place-based diary is a hybrid of a trip-based and an activity-based diary, in which respondents are asked which places they went in chronological sequence across the diary period and are then asked how they got there. The place-based diary attempts to align the respondents' recall process to a more intuitive way of thinking about and recalling daily travel.

Examples

An example of a travel-diary survey is the project called Mobidrive. Mobidrive conducted a six-week continuous travel-diary study with the aim to analyze the rhythms in the behavior of the respondents. The travel-diary survey took place in two German cities of about 300,000 inhabitants each, where a total of 317 persons in 139 households participated in the main study.

A second travel-diary survey example, the Portland Travel and Activity Survey in Oregon, was designed to collect information about where people travel for work, school, shopping, and other purposes to identify and prioritize transportation needs. Survey results provided the foundation to plan the construction of future roads, bridges, sidewalks or bike routes, and changes in transit services, as well as to plan other projects affecting mobility, access to jobs, air quality, and quality of life. In total, 2,747 households were recruited to participate in the study and 1,951 provided travel data.

A third example, the Victorian Integrated Survey of Travel and Activity in Victoria, Australia, is a comprehensive travel-diary survey of how, where, and why Victorians travel. The survey was used to help understand the impacts of changes in transport infrastructure, population growth, and the broader transport and land use planning environment. With a sample size of 17,100 households (43,800 people), respondents were asked to fill in a travel diary for one specified day of the year.

Travel Model Calibration and Validation

Travel model calibration is a series of formulae used in transportation forecasting that estimates the number of pedestrians or vehicles that will travel through a particular destination or road. Travel model calibration is the method used to make models reproduce what a snapshot of data has shown.

Forecasters evaluate current traffic data and base it against factors such as population predictions, employment, and current events to develop such models. Calibration specifically refers to the adjustments of constants and parameters within estimated models to reflect the data previously collected. This, however, is not to be confused with model validation. Validation is the application of the calibrated model and comparing those results against observed data. For example, the calibration data may be data collected in a given year, while the validation data may have been collected from a different year and used to compare against the current year.

Travel model calibration and trip forecasting is important for transportation policy, planning, and engineering. Such data can reveal how large or small infrastructure should be, estimate necessary funding, anticipate social demands, and evaluate environmental impacts.

The Right Data

There are several sources of data that travel models rely upon, including accurate estimates of base year traffic analysis zone (TAZ) household characteristics and employment information, representation of the base-year highway and transit network, a base-year travel survey, and base-year ground counts.

Travel model calibrations are based on socioeconomic and transportation network data.

Socioeconomic data is typically derived from the U.S. Census or American Community Survey and identifies qualities about travelers and pedestrians such as populations, age, race, gender, income, professional industry, place of employment, vehicle ownership, annual income, and rent or mortgage details.

Over time, socioeconomic data becomes unpredictable because of the ever-changing factors that influence it. Transportation network data is considered to be more predictable in this regard. Many models are already in place and simply need updating over time.

The models already in place can serve as validation, and therefore the problem of relying on the same data used to develop the model does not occur. Transportation network data can include topologically integrated geographic encoding and referencing files, commerce vendors, aerial photography, transit route maps and schedules, and transit operation studies.

Two prongs of data represent the first steps in designing a model to forecast travel predictions on a particular road or region. Therefore, reliable predictions depend upon reliable current information and forecasts of both socioeconomic and transportation network data.

In addition to transportation network data, trip distribution data is necessary. Trip length frequency distribution is available as a part of the trip-distribution model set. Information needed for this data includes the average length of a trip and the maximum length of a trip.

The zone radii, or centroid distance parameter, measures the distance in minutes of travel time from the center point of the zone centroid to the nearest point on the perimeter of the zone. Finally, bias factors, such as social and economic factors, impact data. Models take into consideration bias factors when determining validity.

Designing the Model

The significance of designing a proper model and validating its results cannot be understated. The model must yield accurate results to properly gauge driver behavior and traffic performance characteristics.

When designing a travel model, the initial steps are considered the trial-and-error period when the parameters are set by the most reliable

data. Observed data is taken from previously collected travel pattern surveys, which is transportation network data in use. These models can also be completed by using constants and parameters that have been developed for another road or region that is similar to the one in question. This is referred to as “importing.”

One strategy performs calibration in three steps: calibrate capacity at key bottlenecks, traffic volumes, and system performance. Calibrating capacity at key bottlenecks studies areas of high congestion that could lead to delays or long lines. Balancing the designed model against this data will help analysts decide if the plan will meet the high capacity of these target areas or if the parameters must be adjusted.

When calibrating traffic volumes, it is important to be mindful of areas that have multiple routes to different destinations, which may skew data. System performance includes measuring for speed, density, travel time, delay, and queues that are unique to local conditions.

After the models have been developed, they are validated to ensure that they sufficiently perform and reveal data that is intended to properly estimate traffic volumes. This establishes credibility of the model. The models are then compared against traffic counts, such as transit ridership against specific parameters within the area being measured. Such parameters are referred to as screenlines, cutlines, or cordon lines. These lines typically surround a particular area of interest, such as a central business district or a shopping district. Using assumed data against the models is called model sensitivity testing, which determines if the model results are plausible.

It should be noted, however, that no data will ever be entirely accurate. Situations that influence traffic patterns, such as special events, natural disasters, economic downturn, and personal behavior will always alter results, for which all variables cannot be controlled.

Travel Model Improvement Program

Established in 1994, the Travel Model Improvement Program (TMIP) is a program managed by the Federal Highway Administration (FHWA), Federal Transit Administration (FTA), Office of the Secretary of Transportation, and Environmental Protection Agency (EPA). TMIP is administered by the Volpe National Transportation Systems Center (VNTSC).

Mission and Goals

The TMIP’s mission is to support effective use of analytic methods and tools in transportation decision making. It has set the following three goals centering around transportation research, technical training, and technology transfer:

1. To develop and improve analytical methods in response to the increasing demands of planning and environmental decision-making processes mandated by the Clean Air Act Amendments (CAAA) of 1990 and Intermodal Surface Transportation Efficiency Act (ISTEA) of 1991, to better reflect today's lifestyles and travel behavior, and to provide information needed to answer questions confronting today's transportation policy makers
2. To help planning agencies build their institutional capacity to develop and deliver travel data and analyses
3. To support best practices in applying analytical tools to transportation planning decision making

The TMIP is organized into four activity tracks, which are improving current models for near-term use, developing entirely new models in the longer term, improving data collection for travel forecasting, and providing technical training and assistance to help transportation planners improve their models and skills.

Program Guidance and Community

Program guidance is provided by a peer-review panel comprised of experts from the principal audiences of program results. That panel identifies a broad agenda of research needs for the program.

In addition, the Peer Review Program provides an opportunity for planning agencies to invite an expert peer-review panel to review their data, methods, tools, and planning models to ensure that the technical processes they are applying meet the agencies' analysis needs. The TMIP supports peer reviews by assisting agencies in panel assembly, logistics, funding for travel, and, most important, documenting the peer-review meetings and preparing a final report that summarizes the review for the host agency.

Examples of the peer reviews conducted include the Sacramento Area Council of Governments transportation analysis simulation system (TRANSIMS) in November 2009, the Omaha–Council Bluffs Area Planning Agency in November 2010, the Detroit-TRANSIMS in March 2010, the Mid-Ohio Regional Planning Commission TRANSIMS in December 2010, the Association of Monterey

Bay Area Governments in April 2011, the New York Metropolitan Transportation Commission in April 2011, and the Chattanooga–Hamilton County RPC in May 2011.

The TMIP has made a number of technologies and services available to provide interactive learning and improve communication among transportation professionals. The TMIP community resources facilitate TMIP's outreach and capacity-building goals, foster creativity, encourage knowledge sharing, and further strengthen the state of practice in travel analysis methods. The primary resources that make up the TMIP community include TMIP-L E-mail List, Webinars, and Ask the Modeling Experts.

Accomplishments

Since its inception, the TMIP has supported research promoting development of the TRANSIMS, TELUS, UrbanSim, and MOVES software. It has also supported more than 30 peer reviews at state departments of transportation (DOTs) and metropolitan planning organizations (MPOs) around the country. It has provided technical training and hosted National Highway Institute (NHI) training courses, created and maintained a Web Knowledge and Information Exchange (WKIE), and sponsored research leading to hundreds of published reports.

The TMIP has also partnered with important industry organizations including the Association of Metropolitan Planning Organizations (AMPO), American Association of State Highway and Transportation Officials (AASHTO), Transportation Research Board (TRB), and National Association of Regional Councils (NARC).

TMIP Resources

The TMIP maintains a set of recommended reading materials for the transportation industry. It also develops and delivers seminars, Web seminars (Webinars), and workshops on all aspects of transportation analysis, modeling, and simulation. The TMIP also serves as technical contact for some of the National Highway Institute travel-modeling-related courses. The TMIP also maintains a Web site that provides the modeling community updates on relevant news, tools, and upcoming conferences.

Travel Modeling

In the mathematical sense, a model is a description of a system using mathematical concepts and language. This same term could also be described as a mathematical account of something in the real world. Researchers most often use models for the purpose of quantifying real-world systems toward the goal of understanding those systems. Traffic researchers use travel models (also known as travel simulations) for the purpose of forecasting future trends and planning needed improvements.

A number of questions are posed to planners that travel modeling can be useful in solving; these include (but are not limited to) determining the impacts of fee policies in public transit systems, the influence of telecommunications and e-commerce on passenger and freight travel, and the impact of planning on land use and (conversely) the impact of terrain on planning, as well as methods through which the human impact on global climate change may be minimized through proper planning.

Travel modeling may take into account either specifically travel-related data or other regional factors. Travel variables frequently taken into consideration include the number of vehicles on a road, ridership of a railway line, the number of

passengers visiting an airport, or ships using a seaport. Other regional social-oriented factors that could be used in travel models include regional populations, employment rates, and the financial cost of travel.

Travel modeling is critical not only in developing transportation policy, planning public works, and determining the viability of a wide scope of projects but also in determining the social impact and environmental impact of proposed projects. By using travel modeling and associated computational methods, transportation researchers study traveler behavior, the impact of telecommunications on travel behavior, potential trends in transportation demand, and those elements of urban planning that could impact transportation systems.

The past decade has seen a number of changes in the field of travel modeling. These changes include the use of technology toward collecting data on traveler activity, the increased use of disaggregated microsimulations in understanding travel and associated activities on the individual level, and the increased use of dynamic network modeling.

Types

There are a variety of travel models available to transportation researchers. Two of the most commonly used model types are activity-based models and four-step models.

Activity-based models are designed to predict travel trends based on activity on the individual level. Such activities include the behavior of individuals, such as work, leisure, or shopping. The most commonly and successfully deployed model in the United States is the four-step model (or the urban transportation planning process). These models were first deployed in Detroit and Chicago in the 1950s.

In preparation for the process, land use forecasting must be computed. This forecasting includes predictions for the region in question as a whole, and may take into consideration factors such as population growth and concurrent public works projects. This forecasting can include any number of statistical tools, such as single-variable and multivariable regression analysis. Once the process has actually started, the four steps flow in sequential order. They are trip generation, trip distribution, mode choice, and route assignment.

The four-step model starts with trip generation. At this stage, the researcher composing the travel model must make some decisions regarding the variables he or she is studying. Among other factors, the researcher must categorize trips by purpose and the region served by zones. If the model is to be reliable and valid, it must take into account variables such as the terrain of the land, the demographics of the region, and other socioeconomic factors. After these decisions are made, analysts are able to attempt to determine either the frequency of trip origins or the destination of trips in each zone.

The next step of the four-step model is trip distribution. In this stage, researchers attempt to match traveler origins with their destinations. Researchers usually accomplish this task with complex trip tables. With these tables, researchers display travel trends between the various zones within the entire system studied. Historically, this is the least developed stage of the four-step model.

The next step in the four-step model is mode choice. In this research phase, researchers determine through complex computations the proportion of trips between each point of traveler origin and their destination points. These are typically divided into categories based on transportation mode, such as cars, trains, or walking.

The final step to the four-step model is route assignment. In this stage, the researcher attempts to learn information regarding the period between trip origin and trip conclusion; the most commonly studied variable in this stage is total trip time. This stage can be complicated by the fact that travel times within urban transportation systems are most typically a function of demand.

Under the most typical circumstances, the work of the four-step model is followed by a cost-benefit analysis. In this process, the researcher, or the administrators of the travel system, attempt to answer questions such as: Do given routes serve the population that they are intended to serve? Are given routes cost-effective? Are metropolitan tax rates justified, considering the net benefit each urban resident derives from the public transportation system?

Critiques

Travel modeling is not without its critics. Existing criticisms typically address the validity of the model itself or the secondary impacts on the infrastructure development itself. Both mathematicians and

transportation researchers have argued that travel modeling must be improved on the mathematical level. These critics have argued that studies of advanced physics or highly advanced supercomputers may improve the accuracy of traffic models.

Critics outside the research community have argued that travel models do not take the secondary impacts of infrastructure projects into account. These critics point out that infrastructure projects shape the environmental and social terrain in ways that could be harmful to natural systems in the affected area or the people and neighborhoods in that same area. Most of these critics are not inflexible in their stances; they are simply calling for social and environmental considerations to be taken into account by both travel models and their associated projects.

Travel Patterns by Income

Income effects are pervasive in transportation. When travel behavior is broken into its individual subcomponents, such as trip generation, trip distribution, mode choice, and path or route choice, travelers of different income groups behave differently.

To consider the situation systematically, high-income individuals or high-income households have greater resources. For the remainder of this article, high-income households will be considered interchangeable with high-income individuals, although it may be true that not all household members in high-income households have equal access to these resources.

High-income individuals are generally assumed to have higher values of time, and this is a frequent assumption built into transportation demand models. This does not mean that their time is actually worth more than low-income individuals', but they are able to outbid others in various pricing schemes. High-income individuals may also act as if they do value their time more, choosing higher-priced transportation options (such as high occupancy toll lanes) at a higher rate than lower income individuals, provided these options do results in time savings.

Income Impacts on Trip Generation

One consistent finding is that higher-income individuals generate more travel, starting with the perhaps obvious finding that adults in high-income households make work tours at a higher rate than low- or medium-income households. Indeed, some, if not most, high-income households are high-income specifically because two or more adults in the household are workers.

Other activities are also generated at a high rate, though in some cases this means high-income individuals do more trip chaining to satisfy all these activities, making maintenance and/or social/recreational stops on a work tour because they may not have as much leisure time to complete these activities as independent home-based tours. A secondary, somewhat indirect impact is that tour generation is positively correlated with household auto ownership, and auto ownership increases with household income.

Income Impacts on Trip Distribution

Long-term decisions, such as residential location and workplace location, are only beginning to be implemented in travel-demand models, though they have been a feature of land use models for a longer period. Higher-income households are better able to bid for more desirable, higher-priced housing.

In many urban regions in North America, this continues to be manifested with higher-income households predominantly located in suburban locations, though frequently in those suburbs with commuter rail service. This pattern is somewhat inverted in European cities, as well as a handful of U.S. cities, where high-income households locate close to the regional core.

Low-income workers generally have the shortest work tours, although low-income individuals living in regions with serious job-housing mismatches can find themselves having to make long commutes.

The white-collar jobs held by higher-income individuals tend to be concentrated in the central business district (CBD), so high-income workers tend to make commute trips to the regional core. In many regions, because high-income individuals are residing in the suburbs, their work commute typically is longer than low- or medium-income workers.

This is, of course, not the case for high-income workers who live close to the CBD. Increasingly in North America, small high-income households (one or two adults) are shrinking their work commutes, while high-income households with children still tend to be located in the suburbs, and these workers have the traditional longer commutes that bring up the average work commutes for high-income workers.

The trip distribution patterns are not as clear for nonwork trips. University trip distance depends on whether universities are centrally located or not, as well as the proportion of students who live on campus versus those who "commute" to school.

Income plays a relatively minor role in trip length distribution, although it may be the case that, in some regions, a higher proportion of low- or medium-income university students live at home (and incur longer trips) rather than live on campus.

School trips are quite short across all income categories (the shortest of all trip categories), though a relatively small number of children travel longer

High-income commuters are less likely to use transit and more likely to commute by automobile and in single-occupant vehicles. For this reason, they are less likely to make use of shared-ride high occupancy vehicles (HOV) and HOV lanes such as the lanes seen here with the least vehicles, center, on Interstate 95 in Virginia. However, high-income drivers are the most willing to pay tolls if it saves them time, suggesting growth potential for high-occupancy toll (HOT) lanes that allow a solo driver to pay a toll in order to join HOV lanes.

distances to go to private schools. This behavior will generally be restricted to medium- and high-income households.

For shopping, personal business, and social/recreation tours, there generally is no direct connection between income and trip distance. There is, however, an income impact if one considers (and models) mode and trip location as a conjoint decision, since transit trips tend to be shorter than auto trips and walk trips are shortest of all. As detailed in the next section, income plays a significant role in mode choice (and combined mode/destination choice decisions).

Income Impacts on Mode Choice

Controlling for household size and workers in the household, high-income households own the most autos. In turn, owning one or more autos in the household greatly increases the likelihood of driving for all travel purposes, not simply for work commutes. As a related point, the individuals (aged 18 and up) in high-income households typically have a car for their personal use, assuming that they have a driver's license. Thus, the amount of shared-ride, high occupancy vehicle (HOV)

mode observed among high-income individuals is much lower than for low- and medium-income individuals.

In the somewhat extreme case (in the United States, at least) of no car ownership, mode choice is dominated by transit and walking/cycling. Low-income households without autos are often classified as "transit captive," though they may not, in fact, make all their trips by transit.

High-income individuals take transit less than low- or medium-income individuals, though this relative gap is lower for commute trips, especially when a rail mode is a valid option. In many regions, the aversion to transit (among high-income travelers) is highest for local bus and lowest for rail modes; commuter rail in particular serves (and is taken by) high-income workers. Taking that into account, rail is still considered less desirable than driving by high-income travelers.

Low-income individuals have the highest propensity to take transit. This may not necessarily translate into low-income individuals comprising the majority of transit riders, though it clearly does in regions where transit is viewed as unreliable and car ownership is widespread.

Propensity to walk, except for school trips, is closely aligned with household income as well. Low-income travelers tend to walk more and high-income individuals walk less. This pattern does not appear to hold true for cycling trips, however.

Income Impacts on Route Choice

Income only enters mode-choice considerations when there are clear trade-offs between saving travel time and paying higher tolls (or fares), and high-income drivers are the most willing to pay tolls if it saves them time. Not all regions in North America, or indeed Europe, offer these trade-offs and in these regions, income should not play a role in mode choice beyond the initial impact on trip origin and destination. However, an increasing number of metropolitan regions are investigating road-pricing options or more elaborate toll schemes. For instance, high occupancy toll (HOT) lanes are designed to allow a solo driver to pay a toll in order to join HOV lanes, which typically do offer a time savings relative to general-purpose lanes.

As road charges increase, all drivers will seek to divert to lower-priced alternatives, but the diversion will be greater among low- and medium-income drivers. If parking charges are increased, this will have different impacts on drivers, with the high-income drivers the least impacted. Low- and medium-income drivers may ultimately shift to carpooling to split costs or even shift to transit, or they may also adapt by parking farther from their final destination and walking. (Not all travel models can capture this particular adaptive strategy, however.) This pattern also generally holds true for congestion pricing, where high-income individuals will divert the least. However, there is some evidence that low-income individuals may have less flexibility in their work hours than high-income white-collar workers and may divert less than economic theory would suggest.

The more widespread the road charges or toll facilities, the more that regional mode choice will be affected, tilting away from single-occupancy driving and toward other modes. Again, one would expect this to impact high-income drivers the least. Whether this can be considered equitable depends on many factors, including what alternatives are available for low- and medium-income travelers and whether the funds raised through tolling or road pricing are used to support meaningful transit options.

Impact of Better Understanding of Patterns

Planning efforts, particularly those that involve changing the relative price of taking transit versus driving (through tolls, road pricing, higher parking charges, or higher fares) will have different impacts based on income effects. Simply ignoring these differential impacts can lead to serious errors in predicting the overall outcome and even effectiveness of these programs.

While income effects are pervasive in all aspects of transportation decision making, representing these income impacts in mode choice is critical, although reflecting household income and auto ownership is superior in terms of explanatory power if this can be achieved. Even transportation planners who do not or are not able to consider income in their transportation planning efforts may hold onto the concept of the captive transit market versus the choice captive market in order to avoid models that are too sensitive or not sufficiently sensitive to changes in transit service and fares.

Beyond the general desire to better understand impacts of plans on travel patterns, there has been increased interest on the part of the U.S. federal government to ensure that regional transportation plans do not adversely impact minority and low-income populations. These requirements certainly suggest, if not necessarily mandate, the adoption of transportation models that can distinguish low-income from medium- and high-income travelers in order to track the various impacts of plans on different income groups. As many regions have begun to consider how to increase revenues to pay for transportation projects, planners in these regions will be making investigations into raising tolls or implementing road pricing, and at the same time they will be asked to consider affordability of travel, particularly for low-income individuals.

Travel Patterns by Race/Ethnicity

Transportation and transportation policy are often presented in a general sense, in relation to how they affect the population as a whole. However, there exist clear distinctions in the way that various subpopulations use transportation, distinctions that illustrate many of the potential inequalities still present within society. Notable among these are differences in transportation usage by race, ethnicity, and immigration status.

Several aspects of this topic could be explored, including issues of environmental justice and transportation, but this article concentrates on differential levels of access to transportation, usage of different transportation modes, and disparities in commuting times in the United States, in particular.

Key Aspects of Transportation Behavior

To begin, there is the level of access to different transportation modes, referring to the manner by which people get from one place to another. In the United States, the car is king, and most people drive by themselves in order to get to work and also to run errands. Because street networks are ubiquitous, an automobile provides an individual with the freedom to go just about anywhere.

Yet, there are wide differences in travel by racial groups, based on their access to automobiles due to relative disparities in income, driver licensing rates, and other factors such as residential location and transit availability.

Fully 21 percent of black-led households have no vehicle, according to the 2005 American Community Survey. This compares with just 6 percent of white

non-Hispanic households without vehicle access. Hispanic white and Asian-led households fall somewhere in the middle, with 12 percent and 11 percent of households without vehicles, respectively.

Geographic location might help explain some of these variations, but earlier data from 2000 demonstrates that even when location is held constant, African American households are still two and one-half to four times more likely to be without a household vehicle than are white-led households, with Hispanics and Asians in the middle.

Certainly, the availability of mass transit options, such as rail and buses, depends greatly on geographic location. Routes and stations must be developed such that an individual has a reasonable opportunity to get from his or her home to a destination in a timely manner. The availability of transit is quite uneven and remains focused on urban areas with a commitment to transit.

Nonmotorized transportation options such as walking and bicycling are generally available at a low cost to all individuals, but there is a question of distance and safety. Are places reasonably close together and are there available facilities such as sidewalks, bike paths, or easily navigated crosswalks? In this regard, African Americans are more likely to live in densely populated places with greater transit options. Many Asian populations, on the other hand, tend to live more in suburban areas.

Related to the levels of automobile and transit access is the question of modal choice for commuting to work. Modal choice refers simply to which transportation mode—such as carpooling, driving alone, transit, bicycling, or walking—one uses most frequently.

Overall, only 5 percent of Americans utilize transit and another 10 percent choose to carpool. But clear distinctions among racial groups persist, with both African Americans and Asians nearly four times more likely than whites to take transit, according to the 2011 American Community Survey. Hispanics are more likely transit-oriented, but are notable users of carpools, as well. In fact, Hispanics are twice as likely to share a car as non-Hispanic whites.

Immigrants show relatively high levels of both transit ridership and carpool use, and their choice of which mode to use is highly conditioned on time spent in the United States. Each year of residence leads to greater reliance on automobile commuting and less use of transit.

Other mode choices are also affected. According to data from 2007, about one out of four very recent immigrants with four years or less in the United States carpools. Unlike transit, carpooling is available to everyone with access to a car, regardless of where they work or live. Given their lack of access to automobiles, carpooling may be necessary for recent immigrants who do not live and work near routes served by public transit.

While many (but by no means all) immigrants settle initially in inner-city locations, the majority of workplaces are located within the suburbs. Private shared-ride opportunities, including shuttle buses and vanpools, sometimes provide transportation from residences to suburban worksites. With more years in the country, carpool use by immigrants drops off but remains high for several years until finally approaching the levels of U.S.-born residents after 21 years. The choice of walking or biking starts off high among very recent immigrants but falls off rapidly. The initial location of immigrants in so-called ethnic enclaves that include homes, workplaces, and shopping may make walking more convenient. As immigrants establish themselves, they might leave these enclaves for more distant neighborhoods and so increase their reliance on automobiles.

Travel Time

Finally, there is a question of travel time, or how long it takes somebody to get to work. Data from 1980 showed that African Americans had significantly longer commutes than whites, with Hispanics in the middle. Of course, travel times are heavily conditioned on mode of travel, because minority groups are more likely to take transit and because transit takes more time than automotive travel.

But considering just those who travel by automobile, there have been documented differences in commute time by race. Studies using 1990 data demonstrated that, among automobile users, white males had a longer commute, but this was compensated for by higher incomes. African American women, on the other hand, were more likely to suffer long commutes, generally from their inner-city residences to a suburban workplace, but without compensating wages.

The most recent data show continued racial and ethnic differences in travel time. The 2009 American Community Survey indicates that non-Hispanic whites enjoy shorter commute times if they

are driving alone by car. African Americans spend more time in taking public transportation. Some of these differences can be attributed to the location of each group within metropolitan areas and the relative locations of work.

Many of the disparities are likely also related to differences between metropolitan areas. The metropolitan areas with the longest commutes, including New York; Chicago; Washington, D.C.; and Atlanta also happen to have the highest populations of African Americans. This could skew the national figures.

Socioeconomic Status

In all of this discussion, it is important to remember that race, ethnicity, and immigration status are bound up with income levels; minorities and recent immigrants are usually poorer than white natives. In addition, different racial and immigrant populations in the United States tend to be found in larger metropolitan areas, and, within these, concentrated within the more densely populated neighborhoods.

As a result, the distinctions observed in transportation usage are partially correlated with levels of socioeconomic status and geographical location. At the same time, transportation usage still varies even when such factors are controlled for. This demonstrates, once again, that race and ethnicity continue to be a powerful driver of difference within American society.

Travel Patterns of the Elderly

Most industrial societies are aging rapidly; people are living longer but having fewer children. Most people in the industrial world will soon pass their 65th birthday as drivers, and if not drivers, then car passengers. Yet, on average, people lose some of the skills necessary to keep driving safely as they age; many others, particularly women, do not wish to keep driving even though they are objectively competent to do so. The increasing automobility of seniors creates a number of policy challenges.

Most transportation researchers have focused on three substantive areas: the travel patterns of seniors, driving safety, and viable mobility options. Cutting across these areas are differences by gender, race, ethnicity, immigration status, residential location (for example, suburban versus central city), household structure, and income.

Basic Patterns and Changes Over Time

Older travelers take a much higher percentage of their trips in a car, as a driver or passenger, than did comparable-age people in the past. In fact, seniors take a slightly higher share of their trips by car than middle-aged people; older Americans never take less than 75 percent of all trips and 90 percent of shopping trips in a car. Conversely, less than 3 percent of all trips by seniors are made on public transit; seniors are two to three times more likely to walk than to take public transit.

Older travelers today also take more trips than comparable cohorts of seniors did a decade ago. At the same time, older people make fewer total daily trips by any mode than those younger. This difference is often seen as evidence of a mobility loss. Yet all evidence suggests that older people are very mobile until well into their 70s—many have simply

stopped making five weekly work trips, and so their average number of daily trips drops. This is hardly evidence of mobility loss. In fact, older people for at least a decade after they retire make more non-work trips than younger people.

Older people also take longer average nonwork trips than comparable travelers in the past because they have more time to travel, and possibly because they are no longer constrained by the need to conduct these activities near their job or on the way to or from work. Other possible causes for the increase in both the number of nonwork trips and their length may be the convenience offered by the car, living in low-density and rural places where longer trips are necessary, having higher average incomes that are associated with increased trip making, and/or staying in the labor force past traditional retirement age, thus retaining daily work trips that comparable seniors in the past did not make.

Driving Competence and Cessation

Older drivers are among the safest on the road; they obey the law, do not drink and drive, wear their seat belts, and rarely take deliberate risks. Because they take fewer total trips than younger travelers, and often not at peak periods, they have lower per capita crash rates until roughly the age of 80.

However, older people are more likely to die or be seriously injured in a crash of comparable severity than those younger. Moreover, as they age past 75, older drivers on average have more crashes per exposure (that is, miles driven). Many driving skills do decline with age, and most older people will come to a point when they can no longer safely drive.

Older drivers recognize many of their driving deficiencies; they self-regulate, avoiding driving situations they consider dangerous or stressful, such as at night or in heavy traffic or bad weather. However, studies show that not all older drivers accurately recognize their problems; it is not realistic to assume that, as society ages, self-regulation will prevent rising crash rates among older drivers.

There is no reliable and cost-effective way to easily screen older (or younger) drivers for their potential of having serious crashes. There is also a lack of cost-effective methods shown to meaningfully improve the driving of older people; most training or education methods associated with lower crash rates have simply persuaded older people to drive less rather than teaching them to drive better.

Automatically testing drivers who reach age 70 or 75 does not reduce overall crash rates, although it does encourage sometimes capable (often women) drivers to stop driving. Such testing is costly and yields no discernible benefits; New Zealand abandoned this expensive requirement because it had no effect on crash rates. A famous study contrasting two Scandinavian countries, one with rigorous age-based testing (Finland) and one without (Sweden), found that Finland did not have as many licensed older people—but no fewer crashes involving older drivers than Sweden. Seniors in Finland experienced a much higher total fatality rate, though, because when they gave up driving, older people used more dangerous modes such as walking and cycling.

Older people may take in-class driver training, but five decades of studies find little evidence that seniors who attend such classes actually lower their crash rates, although they may lower their rates of getting traffic tickets. This counterintuitive outcome may represent increased driving by those who take such courses because they feel more confident; more driving translates into greater exposure or likelihood of having a crash. Current research focuses on how changes in automobiles themselves (self-braking, for example), as well as changes in the highway system (clearer signs and lane markings, for example), might make driving safer for older people. Given that one out of five drivers on the road will be over 65 within a few decades, it may be important for highway and traffic departments to make the older driver the “designated driver.”

Developing Mobility Alternatives

While seniors are more mobile than comparable people in the past, some seniors do suffer serious and growing mobility problems as they age, as well as declining incomes. The number of seniors who never leave home on one or more days of the week, or who report mobility problems, has grown substantially.

Policy options include expanding mandatory paratransit services for people with disabilities as the population ages, offering more-responsive public transit services (for example, better information particularly enroute, more helpful drivers, being allowed to sit down before the bus starts, routes and schedules targeted to the needs of older people), expanding community-based transportation systems, and supporting volunteer voucher programs (in which eligible older travelers ask someone they

trust to drive them and pay with a voucher subsidized by a public program).

However, older people’s reasons for just staying home may be complicated; the same conditions that can reduce older people’s mobility or impair their driving may reduce their willingness to go out at all. Simply providing transportation may not overcome the physical, emotional, or financial constraints that leave some older people isolated. It is important that transportation options be offered as part of a package of assistance to older people with mobility problems.

Conclusion

Society is aging; the travel needs and patterns of seniors are changing in ways that cannot always be predicted from the largely cross-sectional research already done. The challenge is to identify and implement a variety of approaches that lead to the safe mobility of older travelers now and in the future.

Travel Patterns of Women

Women’s travel differs, often substantially, from men’s; around the world women tend to have different trip lengths, more complicated trip patterns,

different reasons for travel, and less access to the most advanced transportation methods. These patterns are due in part to ordinary sociodemographic characteristics such as income or employment status but they are also related to sometimes complex social, cultural, and psychological factors. Women tend to be poorer, for example, and income determines many aspects of travel choices.

Yet even when women and men have the same personal or household income, their travel patterns may still differ widely. Moreover, while some gender differences in travel patterns have been slowly disappearing, others have stubbornly remained. Even the movement toward parity among the sexes disguises sometimes remarkable travel differences between otherwise comparable women and men in both developing nations and in the industrial world.

A large body of research shows that gender differences in travel patterns around the world can be linked to four inter-related factors:

1. Disparities in income, education, employment, and household resources
2. Differences in access to, and use, of transportation options
3. Social, cultural, and religious norms about both gender-appropriate activities outside the home and about travel choices
4. Personal security and safety concerns

Developing Nations

Women's travel patterns in general are a response to, and a result of, the state of economic development in their country as it interacts with pervasive cultural and religious norms about women's appropriate behavior and access to transportation resources. In developing nations the differences between women and men's travel patterns are wider than in the industrial world, and greatest in the poorest countries. In contrast to average patterns in the industrial world, women in developing countries often spend longer time traveling due to the nature of their jobs, their need to combine household and child care duties with their commutes, and their use of slower modes.

Being forced to rely on slower, more physically demanding transportation modes continues to keep even employed women poorer than men. Income and residential location are significantly related; poor people are often forced to live at great distance

from urban concentrations, creating lengthy commutes. Moreover, the less income a woman makes, the less she is in a position to bargain for access to better household modes of transport. Since lack of transport reduces women's income potential, their social status remains too low to affect the division of transport resources in their own household.

Women in developing nations use different transport modes than men. In urban areas women are more likely to walk or use public transit and less likely to have a car, since ownership and use of vehicles is often a male prerogative. When they do not walk, women are often limited to informal transportation solutions (for example, donkey carts and ped-taxis) because they are cheaper, even if dangerous and unreliable. Women's travel is also restricted by cultural and religious norms. In some countries there are significant cultural barriers to women adopting new technology or certain modes. Moreover, fear of crime, sexual assault, robbery, or harassment constitute a major mobility problem for women in developing countries. Women are often the targets of sexual harassment while walking or riding public transit, exacerbated by inadequate lighting and small, isolated paths connecting where they live to bus stops. Women in developing countries also have safety concerns; as pedestrians they fear falling on poorly maintained roads or footpaths, or losing their loads, or being hit by motorized vehicles.

Developed Nations

While few women in industrial nations face anything like the deprivation of women in the developing nations, there are strong parallels. There are persistent differences between women and men in travel patterns, only some of which can be explained by economic and demographic factors such as employment status, occupation, income, and life cycle.

As the employment opportunities open to women have increased their income, many important travel differences between women and men in all aspects of travel—mode used, trip purpose, trip length, trip patterns—have clearly decreased. In 2006 more of the licensed drivers on U.S. highways were women than men. In 2011, licensing was close to parity among the sexes in the United States. However, women with licenses drive less (measured in miles/kilometers) than men of comparable age with licenses (and the gap grows wider with advancing age).

One of the most persistent differences between women and men is work trip commuting distance. Almost all research shows that women commute shorter distances than men, even controlling for other sociodemographic variables such as income, in every industrial country where data are available. This may result from persistent gender roles; research shows that married women with the most children have the shortest commutes of all commuters, while men's commutes were not affected by the number and age of their children.

Women in the industrial nations in all life cycles made more shopping trips and more chauffeuring ("serve passenger") trips than comparable men. Salaried married women with children made twice as many serve passenger trips as comparable men. Research from many nations shows that women are more likely to chauffeur their children, and it has also been found that organizing chauffeuring duties was considered the mother's responsibility even if she was not conducting the trip. Women also more often trip-chain, that is, link other trips to their work commutes, to drop off or pick up children at school, day care, or recreational activities, or to conduct household duties such as shopping.

These differences, as in the developing nations, are due in part to disparities in income but are not fully explained by income or employment. Some are clearly due to cultural norms about parenting. Many studies find that salaried mothers continually challenge themselves about their parenting duties whereas fathers in comparable situations do not.

In addition, women in industrial nations have different personal security and safety concerns than men. While women at all ages are significantly less likely to have car crashes than men, and are more likely to be law-abiding drivers (not drinking and driving and always wearing their seat belts), they are much more likely to be significantly injured or killed than men in crashes of comparable severity.

Moreover, they also fear falling on sidewalks or being hit by cyclists or people running on footpaths. And even women in developed countries have personal security fears; they report harassment and even sexual attacks in public places and while using public transport modes.

Conclusion

Women, regardless of the level of economic development in their community or nation, have less access to better or faster transportation resources, display different and more complicated travel patterns, and are more influenced by fear of attack or harassment than are comparable men.

These gender differences are a complex response to differential economic resources, societal norms about the use of transport modes as well as household and child care constraints—themselves embedded in a web of cultural attitudes and societal norms. Gender differences are starkest in the developing world because women's opportunities for paid employment are less and their social status so much lower than comparable men's. But the parallels are many and strong.

Researchers suggest that we can address these issues by requiring public projects to conduct gender-specific analyses of the costs and benefits of public expenditures, encouraging more women to enter the transportation planning and research fields, and ensuring the inclusion of gender indicators in transport project design as several European nations have done.

Travel Pricing

Travel pricing is a concept that covers a wide range of policy measures, which involve payment for road access in direct relation to usage criteria rather than paying a fixed network access fee unrelated to the actual use, or paying proxy charges, such as road fuel taxes. More specifically, travel pricing is a term that could be used as a generic synopsis of the cases where a monetary fee is a prerequisite to access part of the road network as a way to regulate traffic congestion growth and its unwelcome consequences.

This pay-to-use road space could vary from a high-speed motorway (or even from a motorway's single lane) up to a city center-wide area of a megacity such as London or Singapore. In terms of operational complexity, travel pricing could be as simplistic as a one-point entry road charging zone that is tollbooth oriented or as multifaceted as a fully automated electronic road pricing system for a whole city or a double cordon system that has been integrated into a much broader local

authority's strategic agenda for improved sustainable mobility.

The Need for Travel Pricing

Travel pricing is a restraining mechanism that has been applied to satisfy the twin objectives of reducing severe road traffic congestion and preventing environmental degradation in urban environments. These remedies could range from straightforward themes, such as air and noise pollution, to more complicated ones, such as the degradation of aesthetically displeasing landscapes.

Travel pricing is also a way to promote healthier and more socially sustainable ways of commuting, such as bicycling and walking; to encourage modal shift to public transport modes; and to provide an incentive for reducing excessive fuel consumption.

Perhaps of equal or greater importance in some situations is another fundamental, but sometimes underlying, motive behind the implementation of travel pricing, and that refers directly to the city economy or, in some particular pricing cases, of wider context to help support a nationwide economy. Travel pricing is gradually becoming an invaluable revenue generator that has the advantage of being clearly and immediately associated with transportation operations by road users. Travel pricing's function as a resource collector could provide the funding basis for transport improvement packages for the cities choosing to introduce and run this as part of their travel demand plans.

The value that travel pricing has is usually the critical criterion for its eventual acceptance in both political and societal terms, and thus the cornerstone for its successful introduction by authorities around the world. This is because travel pricing in all its variations provides institutions with an effective and direct way to deal with the costs associated with operating, maintaining, and expanding a transportation system to meet growing travel demand. Furthermore, it is sometimes the only vital fund-raising apparatus available to policy makers and stakeholders that has the potential to help them overcome the inefficiencies of the centrally governed transportation subsidy operations.

However, any charging program that generally has the intention of reducing the number of private-vehicle trips may be put in an awkward position if it is seen to be raising funds to pay for more facilities for private motor vehicles.

In Los Angeles, the high-occupancy toll (HOT) lane system uses “switchable” transponders for the occupants of the vehicle to indicate the number of people in the vehicle by setting a switch. The toll collection system automatically determines whether a toll should be charged based on the setting.

Types of Travel Pricing

Travel pricing is not a single policy or a technical measure with a one-dimensional character but rather a collection of various road movement charging strategies. Namely, these could be congestion pricing (peak hour/nonpeak hour), variably priced traffic lanes, express tollways, area-based or cordon-based road pricing, variable tolls, electronic road pricing, toll roads and toll motorways (tollbooth-operated or automated), and mileage-based charging.

There are four broad categories into which the travel pricing strategies could be organized:

1. Variable tolls on entire roadways
2. Variably priced lanes that are founded on having variable tolls on separated lanes within a highway, such as high occupancy toll (HOT) lanes or express toll lanes
3. Zone pricing that is either a variable or fixed charge drivers need to pay while traveling within or into a designated city area (usually known simply as congestion charging or pricing)
4. Mileage-based charges on all roads within an area (area-wide charges), which may vary by the level of traffic congestion and requires advanced technology to be applied

The two basic criteria that allow these different strategies to fall under the same broad policy classification are (1) the financial fee to access road space that is being imposed on the drivers, and (2) the fact that these measures serve in a significant degree the goals of relieving traffic congestion, mitigating environmental impacts of travel, and funding transport operations that otherwise could not have been realized.

Societal Implications for Travel Pricing

Despite its potential to benefit societal well-being in terms of mobility, sustainability, and transport investments, travel pricing in all of its forms suffers from low public acceptability. Especially if no regulatory traffic policy was used to manage road space before its implementation and thus was free, the measure will have strong public opposition to overcome.

Many people, especially immediately before the introduction of the measure or before a referendum that is to decide the future of such a pricing mechanism, tend to dismiss its pro-social value in terms of reducing traffic congestion and improving environmental conditions and focus solely on its “penalizing” and “socially exclusive” character. The restrictions of access implied by the toll requirement are seen as being against the notions of freedom and choice. Travel pricing can be easily labeled by many people, and more likely by those who have not experienced the measure before, as an additional form of prejudiced taxation designed to make them carry one more financial burden.

Nonetheless, various research studies have proven that as car users become more accustomed to road pricing measures, they are far more likely to support them because of the travel savings they experience because of the reduced traffic congestion.

Moreover, other transport users see the potential of travel pricing to support their preferred modes of transportation by providing, first, a more livable urban environment that can adopt in a more effective way more sustainable forms of traveling, and, second, a funding instrument that could finance infrastructure and services dedicated to alternative transportation.

Travel Speed Models

Motor vehicles are major contributors to air pollution, and, as a result, there is increasing interest in finding accurate ways to model vehicle emissions. Accurate information about emissions is necessary for many purposes, including transportation planning, to measure the effects of policies, and to estimate environmental impact.

One approach to the problem of estimating emissions has been the development of travel speed models, which are based on the understanding that speed of travel is one key factor in the quantity of emissions produced by a vehicle. Among travel speed models, the average speed model, based on the average speed of a vehicle over an entire trip, is commonly used. However, the average speed model also has drawbacks, and researchers have developed more sophisticated variations on the average speed model in order to ameliorate its perceived shortcomings; in addition, a more complex model based on instantaneous speed is also available.

Emissions Modeling

Motor vehicle exhaust includes many harmful air pollutants, including carbon monoxide (CO), nitrogen oxides (NO_x), sulfur dioxide (SO₂), volatile

organic compounds (VOCs), and particulate matter (PM). Estimation of the amount of these compounds produced by vehicular travel in an area is an important aspect of transportation planning and environmental impact assessment, and a variety of models have been developed to aid in this process.

In broad categories, the available models include aggregated emission factor models, which look at only broad categories of driving (for example, urban, rural) and broad categories of vehicles. Average speed models are more sophisticated and incorporate information about the average speed of a vehicle over a given trip. Traffic situation models are even more complex, including information about traffic situations (for example, free flow, congested), as well as average speeds. The most sophisticated models are instantaneous models, which combine information about instantaneous speed and acceleration to calculate the rate of emissions.

Despite the fact that more sophisticated models are available, average speed models are still popular in emissions estimation. Three reasons for their continued popularity are that average speed models are relatively simple and easy to understand, the data required to use them is commonly available, and software to compute them is readily available and often free.

However, average speed over the length of a trip is a relatively crude measure; for instance, the same average speed could be achieved by driving at a consistent pace, or by periods of fast and slow driving with frequent stops, and the fuel consumption and emissions patterns for these two modes of driving would be expected to be very different. This drawback is more obvious with lower speeds and urban driving, as opposed to high-speed, highway driving.

Examples of software to compute emissions using average speed models include MEET (Methodologies for Estimating air pollutant Emissions from Transport), developed in Europe to estimate energy consumption and emissions of various pollutants with different modes of transportation, including road, rail, water, and air; and COPERT, a widely used model now in its fourth version (COPERT IV), which was developed to calculate emissions and fuel consumption by different types of vehicles and which estimates emissions of both regulated and unregulated pollutants.

Instantaneous models were developed to provide a more detailed description of emissions by

gathering data in short intervals, typically one second in length, and relating emissions rates to vehicle operation during those intervals. They are particularly useful for microscale models, such as modeling air quality on a particular stretch of road, while average speed models are more useful for macro-scale models. The chief disadvantages of instantaneous models are the amount of detailed data required to use them, the expense involved in collecting such data, and the difficulty of measuring emissions accurately on so small a scale. If the information supplied to an instantaneous model is not accurate, this may eliminate any potential benefits of using the more complex model.

The Traffic Energy and Emissions (TEE) model was developed to address some of the deficiencies of the average speed model. It may be considered a “corrected average speed model” because it is still based on the average speed of a vehicle but also considers the effects of road congestion on emissions. The TEE model includes a corrections factor using information about traffic signals, link length, and traffic density, as well as average speed, to estimate the amount of time spent in different phases of driving, including acceleration, deceleration, idling, and cruising.

Results

Looking at “hot” exhaust emissions (that is, emissions after an engine has reached operating temperature), researchers found a U-shaped relationship between average speed and emissions. Looking specifically at NO_x emissions, they found that emissions were highest in the range of 6 to 12 miles per hour (10 to 20 kilometers per hour [km/h]) and over 74 miles per hour (120 km/h) and lowest in the range of 37 to 50 miles per hour (60 to 80 km/h).

Several studies have compared estimated emissions as calculated by various models with actual emissions measured by various sensing methods. In a series of tests in Sweden, the COPERT III model produced estimations close to those measured for CO and NO_x , but had poorer agreement for CO and hydrocarbon (HC) emissions. Measurements of emissions conducted in the United Kingdom, gathered by driving vehicles continuously through tunnels and collecting measurements from several points along the way, produced results showing that several models, including COPERT III,

predicted higher emissions than were actually measured during vehicle operation in the tunnels. This was particularly true for predicted NO_x , and greater variation between the predicted and measured NO_x emissions was found for heavy-duty vehicles than for automobiles.

Travel Surveys

At any given moment, travel is taking place across the United States. A snapshot of travel will show people traveling for different reasons, by different travel modes, and between different origin/destination (O-D) pairs. The purpose of travel surveys is to capture information about the various types of travel and supplement it with demographic details about the travelers in order to recreate this snapshot.

The objective is to replicate these patterns in travel demand models and to forecast travel patterns for long-range transportation planning efforts. Several types of travel surveys are conducted across the United States. Regardless of the type, at the core, the surveys capture key elements of travel: origins and destinations, time of day, trip purposes, and travel modes. Types of travel surveys include the following:

- Household travel surveys
- Commercial vehicle surveys
- Workplace surveys
- Special generator surveys
- External travel surveys (also known as cordon line surveys)
- Transit on-board surveys
- Visitor surveys
- Special surveys of subsets of travelers, such as long-distance personal travel surveys, freight surveys, and surveys of bicyclists

The history of travel surveys began with the 1944 Federal-Aid Highway Act, which authorized funding for urban highway extensions. Around this same time, the Bureau of Public Roads issued the *Manual of Procedures for Home Interview Traffic Studies*. The first travel surveys were conducted in Tulsa, Oklahoma; Little Rock, Arkansas; New Orleans, Louisiana; Kansas City, Missouri; Memphis, Tennessee; Savannah, Georgia; and Lincoln, Nebraska.

Over time, the methods used to conduct these surveys have evolved as a result of technological advances, societal trends, and travel demand modeling needs. Travel survey methods are currently evolving to reflect advanced technology that can obtain the travel behavior details with a reduced respondent burden.

The most frequently conducted travel surveys are household surveys, commercial vehicle surveys,

external station surveys, transit on-board surveys, and workplace surveys (in that order). An overview for each of these is presented below.

Household Travel Surveys

The travel behavior details captured in household travel surveys can inform the following questions:

- Why do people travel outside the region?
- Where do the people who work in the central city live? Are they centralized enough for express bus service?
- Where are the best park-and-ride locations?
- Who trip chains? Where do they stop? What type of mixed-used developments would help reduce vehicle miles traveled (VMT)?
- Where are the best locations for electric vehicle recharging stations?

The general approach entails a random recruitment of region households, documenting household member demographics, and asking all (or a portion of) household members to record all trips made for a 24-hour or 48-hour period. The typical sample size is between 1 and 2 percent of the universe of households in a region. Current technology includes computer-aided telephone interviewing (CATI), Internet-based computer-aided self-administered (CASI), postal mail, and passive collection through global positioning data obtained from provided units or via a respondent's smartphone.

In addition to this base collection of data, recent travel surveys have included supplements that focus on a specific population subgroup or mode-usage group, such as university student surveys and long-distance travel surveys.

Commercial Vehicle Surveys

This type of survey documents the origins and destinations of travel by vehicles owned by businesses rather than by households. Typical data looks at route usage, intra- versus inter-regional travel, trip length frequencies, and cargo/transport types. Of particular interest is how these movements vary by truck type.

As with household surveys, businesses are recruited and a subset of their fleets sampled. Drivers of the sampled vehicles are asked to keep a log of

all stops made (including for personal reasons) for a 24-hour period. GPS data is sometimes substituted for the paper log.

External Travel Surveys

External travel surveys are also referred to as “cordon line surveys.” These surveys are designed to document travel into and out of a region. Historically, these surveys were conducted at specific points on the roadway network that led into or out of the region (hence the name “cordon line”). Cars were stopped, interviews conducted, and data collected. As traffic volumes and safety concerns grew, the methods evolved to the current use of video license plate capture and transcription; emerging technologies include Bluetooth readers.

Transit On-Board Surveys

Transit on-board surveys document the use of the transit system by riders. They are designed primarily to document origins and destinations of travel, transfers, and a small amount of demographics. Bus trips from across the system are randomly sampled.

The “universe” is documented through counts of how many people board and alight from each vehicle across all routes during a given time period. Traditionally, these surveys were conducted using pen and paper; surveyors distributed the surveys as passengers boarded and collected them as passengers alighted. Now, handheld tablets and other devices are used to conduct the surveys. Sometimes the full survey and sometimes basic information is collected and the remainder is conducted via Web or telephone.

Workplace Surveys

Similar to external travel surveys, workplace surveys intercept people as they arrive at randomly sampled employer locations throughout a region. The respondents are categorized as employees or visitors to the site, and questions are asked regarding origin and destination of travel, home location, trip purpose, and so forth. These surveys are commonly conducted using tablet computers for immediate entry of responses, with real-time geocoding of the origin and destination data.

Trip Chaining

A trip chain is a sequence of trips taken to pursue different activities. A simple trip chain might take the form of home–activity–home, namely, a trip chain with only one stop and two trip legs. Different taxonomies of multi-stop trip chains are possible, depending on the trip purpose and mode of travel. For example, a sequence of trips might be considered a shopping-trip chain or work-trip chain because work and shopping activities are both included. These trips may be taken by car only or a series of modes (e.g., walk, carpool, transit, etc.); the latter case may also be considered a mode-chaining travel behavior because it involves more than one mode.

In trip chaining, trips may be taken by the same person or different persons in the same or different households. In addition, socioeconomic and demographic characteristics (for example, age, gender, income, auto availability, multiple-worker households, and presence of children in the household) as well as transportation system changes may play a role in the realization of different trip-chaining patterns.

A one-worker household might reach five destinations within the same trip chain with six trips. A second household might reach only three destinations in six trips. It appears that bundling more trips

in a single chain results in a more efficient behavior. Some of the unintended consequences of longer trip chains may include longer commutes and longer morning and evening peak travel periods.

Trip-chaining behavior has important implications for travel forecasting. Traditionally, in urban travel forecasting, different trip purposes are estimated separately for home-based and non-home-based activities before combined and assigned to transportation networks.

The underlying assumption is that each trip from one location to a second location is independent of a subsequent trip from the second location to a third location. In that assumption, when trip-chaining behavior increases—given a constant total number of trips—the number of estimated home-based trips would be underpredicted while the number of estimated non-home-based trips would be overpredicted. It is important, therefore, to understand and account for trip interdependencies in trip-chain formation to improve the sensitivity of travel demand forecasting models. Considerable effort has been devoted to the study of trip-chaining behavior and has resulted in conceptual and methodological advancements.

Descriptive Analysis, Exploratory Studies, and Econometric Models

Standard descriptive tools such as tables of frequencies, histograms, and diagrams, as well as classification and regression, have been widely used with travel diaries and have provided empirical evidence of trip-chaining behavior. Other econometric models used include hazard models in order to account for the continuous nature of the decision-making process underlying activity performance. These techniques have uncovered interdependencies among socioeconomic, demographic, spatial, and other factors (for example, sequence, duration, nature, and location of stops) that affect trip-chaining behavior.

Such approaches have shown evidence of a higher propensity of trip-chaining behavior among multiple-worker households, and that these individuals had a higher propensity to make simple work trip chains when work trips are scheduled in the peak period. Female travelers have been shown to have a higher propensity to trip chaining in the midday in suburb-to-suburb trips, contrary to male drivers on the way from the suburbs to the city.

Suburbanites with lower accessibility to destinations were found more likely to exhibit trip-chaining behavior. Furthermore, factors such as life cycle stage, marital status, gender, employment status, education, income, the presence of children, and residential density were important determinants of trip-chaining behavior.

Activity-Based Models

The activity-based approach to travel demand analysis envisions travel as a derived activity that links, spatially and temporally, other activities in which people engage. A variety of themes have been explored in trip chaining: scheduling time and space of activities by individuals, the interdependencies between one individual and another in the same household, interdependencies between the activities in which one participates, patterns for various days of the week, and so on.

If, for example, a traveler uses the public transit system to get to work in the morning, then the same traveler excludes the possibility of doing, on the way home from work, certain things that might require a car. In addition, if another traveler cannot participate in some activity on a particular weekday, that person might need to reschedule that activity to a different day of the week or, possibly, some other member of the household might be able to undertake various tasks.

With respect to the methodology used, the main concern in the activity-based analysis is to arrange a given set of activities undertaken by an individual or household. This arrangement, if seen as a problem of activity scheduling, resembles the traveling salesman problem that has received much attention in the operations research literature. A number of mathematical programming, combinatorial, and heuristic methods are available. In addition, activity chaining has been seen as a subproblem of the individual activity program-generation problem.

Distinct activity patterns are usually generated by cluster or factor analyses of household socioeconomic and travel data, and are subsequently related to travel frequency and purpose, household composition and lifecycle status, and household economic factors.

Entropy-Maximizing and Gravity Models

The entropy-maximizing approach is deterministic in nature and treats spatial interactions in general,

Figure 1 Decision process for intermediate trips

Source: Paul Metaxatos.

and trip chains in particular, as continuous flows. The approach results in an equivalent optimization problem that gives the gravity model as a solution. On the other hand, the gravity model is probabilistic in nature and treats spatial interactions as discrete events. Both approaches can be included in the traditional urban travel forecasting procedure.

The underlying trip-chaining decision process is illustrated in Figure 1. In this example, a trip chain starts with a high-priority trip, such as the trip to work (0, 1). On the way, if a traveler needs to stop at the dry cleaners, a suitable destination would be chosen conveniently for the trip from 1 to 2. Therefore the trip from 0 to 1 is now via 2 (that is, there are now two trips, one from 0 to 2 and one from 2 to 1). Similarly, either leg 0 to 2 or leg 2 to 1 could be interrupted by another intermediate destination resulting in trip chains 0, 3, 2, 1 or 0, 2, 4, 1, respectively, and so forth.

This approach is similar to the order in which one might fill out an appointment book; work trips are filled out first, medical or other business appointments next, stopping for gas or a convenience store last. Therefore, the choice of destinations is made in a certain order over time, but this order need have little to do with the order of the destinations in the trip chain. Destinations, rather, are prioritized by the order in which the decision was taken or by the importance of the decision.

Thus, modeling can proceed in steps. The choice of the highest-priority destination would be modeled first. At the next step, the choice of an intermediate destination would be modeled. At the next

step, an intermediate destination on one of the previously determined trips would be considered. Therefore, for modeling purposes, it is enough to consider how a single intermediate destination or stop is chosen.

The behavioral implication of this approach is that the terms *mandatory activity* and *discretionary activity* are viewed as relative terms with respect to the underlying decision process. A doctor's appointment, for example, is a discretionary activity with respect to going to work, but mandatory (or less discretionary) in comparison to a visit to a fast food restaurant.

The process above can be operationalized using the probabilistic threshold-choice theory. Within this theory, an individual balances the utility derived from a stop at an intermediate destination against the increase in travel cost incurred, but is otherwise indifferent to variations in travel costs (for example, distance, time, effort, etc.) if and only if anticipated travel costs do not exceed the individual's current threshold level. The choices are then undertaken stage by stage only for the allowable threshold level, and there is a genuine possibility that any given trip considered by the individual may not be taken. The threshold-choice theory assumes only partial information about individual behavior. If, for example, all that is needed is a six-pack of soda, then it is not assumed that a commuter knows the optimal location to buy it. Thus, from a behavioral point of view, the researcher pursues a satisficing rather than a maximizing theory of individual behavior. Moreover, the theory does not assume any explicit search process involved in the choices of destinations.

Under some general independence conditions, it can be shown that larger costs incurred during a deviation for an intermediate activity will reduce the probability that the traveler's threshold levels will exceed these values and reduce the probability of a realized stop. In other words, threshold behavior reduces the mean frequency of potential intermediate stops to a smaller mean frequency of realized stops at intermediate destinations. Moreover, it can be proven that the mean realized single-stop trip-chain frequencies are representable by monotone and, in particular, exponential gravity models.

Markov Processes

Stochastic processes, and in particular Markov processes, have been used to model the sequence

of decisions involved in trip-chaining behavior. Markov models have been developed either as stand-alone models or as models that operationalize activity-based arguments in simulation efforts. The essence of the approach is to estimate the transition probability matrix that indicates functional connections or sequences between activities, as well as strengths of linkages between origins and destinations. Usually, trips from and to home and different activities, and between activities, are structured as an absorbing Markov chain in which one state, the return-home trip, is absorbing and all other states nonabsorbing.

Discrete-Choice Models

The disaggregate utility maximization framework has also been applied to multi-stop, multipurpose travel behavior. In this framework, discrete-choice models are used to develop a sequential model where successive destinations are chosen independently of one another while capturing the effects of past and future travel choices on present travel decisions.

The basic theoretical argument governing the formation of trip chains within this framework is the consideration of the decision for nonwork travel behavior as a choice from among a set of feasible daily paths. Time and income constraints limit both the coordination of trips and the choices of destinations. A condition can then be derived that equates the marginal rate of substitution between linked and unlinked trips with the ratio of their generalized time and travel costs. An increase in income, for example, would thus result in higher opportunity costs and a greater propensity to form trip chains.

Simulation Methods

Increasingly, researchers are attempting to operationalize the activity-based approach, mainly using simulation models to handle the behavioral dimensions of information acquisition, information representation, information processing, and decision making. Simulation methods can relax the intractability of analytical models when there is need to incorporate more complex theoretical notions.

It has been argued that regulating trip-sequencing, route, and destination choice by distance or other attribute considerations either in a sequential or a simultaneous decision-making framework will

remain ultimately an ad hoc heuristic, which is very difficult to represent in a detailed analytical model.

The counterargument is that simulation models offer an attractive alternative because observed relative frequency distributions can be used to categorize sample respondents into behavior types. Such a framework would then allow the utility of alternatives to change depending on past stops or future stops for planned trips.

Trip Distribution Models

Trip distribution models estimate the expected number of trips T_{ij} from an origin i to a destination j . These origins and destinations can be traffic analysis zones in an urban area or points, such as airports, household and employment locations, schools, and so forth. Trip distribution models are used widely in transportation planning as part of the urban transportation modeling system (UTMS). In fact, trip distribution models are one the four model components (that is, steps or stages) of the UTMS.

Taxonomy

The long history of trip distribution models has resulted in different methodological modeling frameworks. Thus, trip distribution models can be

considered as probabilistic in relation to deterministic, aggregated vis-à-vis disaggregated, and static vis-à-vis dynamic models.

Deterministic trip distribution models have been developed as optimization formulations in mathematical programming (for example, as minimum cost models subject to origin, destination, entropy, and cost constraints). Such formulations are adequate to describe overall origin-destination travel patterns when cost or time minimization is the dominant behavioral consideration (for example, among morning commuters going to work).

Additional deterministic formulations have been proposed within the classical microeconomic paradigm of utility-maximizing choice behavior subject to budget constraints. Under various forms of utility functions, the resulting demand function takes the form of a gravity model. Other such efforts have introduced interaction costs (for example, travel time) directly into the utility function. Such approaches require strong assumptions about individual choice behavior and are difficult to test in practice.

More generally, however, traveling from place to place involves a multitude of individual decisions that defy any attempt at deterministic description, to say nothing of prediction. As a result, various probabilistic frameworks have been developed.

One of the earliest models proposed in this regard is Stouffer's "intervening opportunities model," which has been shown to be a special case of a gravity model. Alternative probabilistic approaches employed Luce's theory of individual choice behavior. Additional efforts applied McFadden's multinomial logit model, which can be shown to yield gravity models with exponential deterrence functions—for example, of the form

$$T_{ij} = A_i B_j \exp(-k \theta_{kij}),$$

Another type of random utility approach used Simon's satisficing principle in which individual decisions to interact in space (for example, travel) are modeled by a probabilistic threshold variable depending on relevant measures of spatial separation (for example, travel distance, travel time, etc.).

Probabilistic theories based on statistical equilibrium concepts have been proposed. The essence of the approach is that the most probable state of microspatial interactions can lead to very regular

patterns of macro interaction behavior that are exactly representable by exponential gravity models. It is interesting to note that most trip-distribution models developed are static, implying a shift from one stationary (or equilibrium) state to another. In dynamic contexts, gravity models have been used to describe state transitions in Markov processes.

Disaggregate trip distribution models, also referred to as destination choice models, can be developed as individual choice models (for example, logit models, probit models, etc.) to predict the probability that an individual will choose to travel to a particular destination as a function of individual and destination characteristics.

One of the main issues in this regard is the definition of destination alternatives in the relevant choice sets. This task is more feasible with particular types of trips (for example, shopping trips where a store or a class of stores can be identified). For other types of trips (for example, recreational trips, nonwork trips, etc.), such alternatives may not be easy to identify. In those cases, it may be possible to further disaggregate trip purposes to more elemental dimensions.

Aggregate trip distribution models, on the other hand, do not consider the characteristics of individual travelers and predict the probability of travel between zones as a function of average origin, destination, and origin-destination separation (for example, travel distance, travel time, travel cost, etc.) measures. The most frequently used aggregate trip distribution model is the gravity model, which in its most general formulation takes the form

$$T_{ij} = A_i B_j F_{ij}.$$

The exponential gravity model, in particular, can be written as a logit model. Doubly constrained gravity models, for example, can be viewed as two interlocking choice models; that is, choosing a destination location given an origin location, and choosing an origin location given a destination location.

Estimation

Disaggregate trip distribution models estimate the expected number of trips to destination places using travelers or households as distinct observations, thereby avoiding aggregation bias for the estimated parameters. In addition, disaggregate data at the personal or household level are suitable for market

segmentations where individual observations are classified according to their socioeconomic characteristics, and a separate model estimation for each such classification or market segment. Maximum likelihood estimation methods are used to estimate the model parameters.

Issues that need to be addressed in the estimation of a destination choice model include, first, the generation of relevant destination choice sets of each individual observation possibly by a separate model. In this case, the choice set is a subset of all available destination alternatives from which the traveler chooses the utility-maximizing alternative destination.

The process permits individuals to have different or common classes of destination choice sets for the same trip purpose. In practice, deterministic or random constraints at the personal, household, and societal level are imposed to limit the size of choice sets to manageable levels.

Second, disaggregate trip distribution models generate disaggregate predictions that must be aggregated for use in policy analysis. Alternative procedures for aggregating the predictions of disaggregate models include (1) the summation-integration approach, (2) the classification approach, (3) the naïve approach, (4) the simulation approach, and (5) analytic approaches. Note that inherent in all statistical aggregation procedures is the fundamental trade-off regarding the choice of spatial aggregation units: suitably small to ensure spatial homogeneity but sufficiently large to allow meaningful statistical sampling.

Estimation of gravity models in urban transportation planning is usually done using maximum likelihood methods. This is because the number of origin and destination zones is very large and, consequently, most of the observed flows are zero valued.

In particular, maximum likelihood estimation of Poisson gravity models (in cases where the available observed flows are Poisson distributed) is very robust; its robustness stems from the many types of asymptotic results that establish the Poisson distribution as the unique limiting form for a wide range of interaction processes when the population size increases and the overall influence of each individual interaction decreases. On the other hand, when there are not too many zero-valued observed flows, linear least squares methods may also be used.

Four types of gravity models have been identified: unconstrained, origin-constrained, destination-constrained, and doubly (or origin and destination) constrained. When origin and destination trip totals are not available in the forecast period, the corresponding constraints and the corresponding parameters, which are the Lagrange multipliers (in the maximum likelihood estimation), are dispensed with and unconstrained gravity models are obtained.

Similarly, if only the origin (destination) trip totals are available, the constraints for the destination (origin) parameters can be removed, and origin- (destination-)constrained gravity models are obtained. If both origin and destination totals are available, a doubly constrained gravity model is obtained.

Forecasting With Trip Distribution Models

Disaggregate trip distribution models are developed to predict the destination choice for individual travelers. Because policy decisions affect groups of travelers, or even the entire population of a region, it is important that these models can predict the aggregate travel demand between pairs of destination locations. Methods to aggregate individual predictions are available.

Forecasting methods with aggregate trip distribution, especially gravity models, are also available. Four distinct cases have been discussed: (1) when forecast travel costs are exogenously available, and all origin-, destination-, and separation-based parameters remain unchanged in the forecast period from the base period; (2) when forecast travel costs and separation-based parameters are available from the base period, and destination-based parameters and origin totals are exogenously available; (3) when forecast travel costs and separation-based parameters are available from the base period, and origin-based parameters and destination totals are exogenously available; and (4) when forecast travel costs, separation-based parameters, and origin and destination totals are available.

Application

In the application of disaggregate trip distribution models, it is critical that several types of data are available: (1) traveler- and trip-related attributes that may influence the choice of a particular destination (for example, income, auto ownership/

Trip distribution models are a component of the traditional four-step transportation forecasting model. This step matches traveler's origins and destinations to determine the number of trips going from each original location to each destination. Traffic analysis around busy areas such as the Washington Dulles International Airport, shown here, can determine many factors regarding the design and layout of the airport itself and the surrounding areas.

availability, trip purpose, travel party size, time of day of travel, etc.); (2) attributes related to destinations available to the traveler (for example, travel time and costs, shop type, job category, central business district/city/suburban indicator, etc.). Such data will decide the suitability of model structure (for example, multinomial logit model, nested logit model, etc.).

For example, in a regional application, it may be desirable to estimate the travel demand at prominent destinations. In this case, the overall destination choice may be sequentially estimated by a nested logit model where the “logsums” of the prominent destinations would “inform” the regional work- and nonwork-destination multinomial logit-choice models. In practice, it is not uncommon that the choice of destinations is determined jointly with the mode choice for different trip purposes.

On the other hand, applications of gravity-based trip distribution models are numerous in both passenger and freight travel demand forecasting. In a particular application in freight demand modeling, it was assumed that the behavior of each shipping firm can be considered a very small

interaction process and that the resultant overall interaction process (that is, the realized pattern of origin-destination commodity shipments) can be considered the superposition of all these individual firm-based processes and thus characterized by gravity models. This application obtained an excellent model fit during estimation, as well as small variances and small standard errors of the flow estimates, which provided the basis for measuring the level of accuracy of the origin-destination estimates.

Context-Sensitive Destination Choice

Both the multinomial logit and the gravity model have the “independent of irrelevant alternatives” (IIA) property. In the context of trip distribution models, the IIA property implies a strong form of context-insensitive behavior by travelers, in the sense that the relative likelihoods of choices among pairs of destination choices are independent in the presence or absence of any other destination alternatives. As a result, the variety of models that have been developed to overcome this restriction can be thought to involve a context-sensitive behavior.

Disaggregate trip-distribution models that do not have the IIA property include the generalized extreme value (GEV) class of models (for example, the nested logit model, the paired combinatorial logit model, etc.), as well as other generalizations of the multinomial-logit and probit models.

On the other hand, gravity models can also be generalized to relax the IIA property. One way this is done is by assuming that prominence effects tend to enhance the likelihood that a particular destination location (for example, a specialty store) will be chosen. Such prominence effects are attributable to dissimilarities between choice alternatives.

Another way that gravity models dispense with the IIA property is by assuming that spatial interaction behavior involves a hierarchical interaction process in which a relevant cluster of destinations is first selected (or perceived) by the traveler, and then a specific destination within this cluster is chosen.

Trip Generation Rates and Models

Trip generation is the first step in the classical four-step transport modeling sequence (trip generation, distribution, modal split, and assignment). Its objective is to predict the trips—and more generally the units of measure of movement, like tours—that will be made by the residents of the study area. Although personal trips account for the majority of urban trips (more than 80 percent), trip generation is also a part of freight models.

In principle, this step is very simple. Trip generation usually outputs two sets of trip ends: the number of trips originating in (trip productions) and the number of trips destined for (trip attractions) each of the zones of the study area (also referred to as traffic analysis zones, or TAZ). Personal trip productions are usually determined as a function of socioeconomic variables like income, family size, household structure, and car availability; attributes of TAZ like value of land and residential density; or other (non-residential) land use information like some measure of accessibility.

Personal trip attractions are determined as a function of zonal employment and/or roofed space available for industrial, commercial, and other services. Freight trips are usually determined as a function of the number of employees, the number of sales, roofed area, total area, and so forth. It must be noted that even if it is one of the more used explanatory variables, the explanatory power of car ownership has declined over the years due mostly to its universality.

In order to properly quantify the movements within a study area, a definition of the unit of measure is needed. There is no consensus regarding the definition and/or nomenclature of the unit of measure of movement.

The simplest unit of movement is a stage, which is a continuous movement with one mode (vehicle) of transport. A trip is a continuous sequence of stages between two activities. A journey is a sequence of trips that start and end at the same location. A tour is a sequence of trips that start and end at the home of the relevant person. Trip generation is a generic denomination of models that may use these different units of measure of movement.

Segmentation of Trips

To strengthen the explanatory power of trip generation models, trips are often segmented by purpose (i.e., modeled separately with one model for each trip purpose). This segmentation allows for an easier definition of the relation between the characteristics of individuals or TAZ with the number of trips (e.g., number of workers to explain commuting). Usually, the following purposes are considered: work, education (sometimes segmented further by school level), shopping, social, and recreational, among others. Work and education trips are often considered as compulsory (mandatory) or less flexible, while trips for other purposes are viewed as discretionary (optional).

Another segmentation commonly used is based on whether one of the ends of the trip is located at the home of the trip maker. It is then possible to distinguish between home-based (HB) and non-home-based (NHB) trips. This segmentation allows for two different approaches in the characterization of trip ends for HB trips. In the first one, trip ends are directional. If we take the example of trips to work, trip production for HB work trips, for a given TAZ, consists of the number of trips beginning at home in the TAZ for which the destination is at work somewhere within the study area. Trip attractions, for a given TAZ, correspond with the number of trips having this TAZ as work destination for which the origin is somewhere within the study area.

In the second one, the direction of trips is not taken into account. Trip production is associated with the home end of HB trips (home being the

origin or destination). Trip attraction is associated with the other end of HB trips (this "activity" end being the origin or destination). For NHB trips, the directional approach is generally used and no segmentation by purpose is considered, as these trips only amount to 15 to 20 percent of all trips.

The growing importance of NHB trips casts some doubt on the relevance of HB trip purposes for analysis. For example, if a person drives his or her children to school and then goes to work, an approach in terms of HB trips will only acknowledge the school-based portion and the trip to work will be counted as an NHB trip. The main purpose of the trip, that is, work, is therefore lost. In contrast, an approach in terms of tours retains information on the main purpose of the tour. Given that some trip purposes are more constrained than others, it is possible to assign a single purpose to a tour in a hierarchical manner.

The purpose of the tour is work if this purpose is present among the trips included in the tour. If not, then it is education if this purpose is present, and so on, according to the following hierarchy: work, education, shopping or personal matters, leisure, other.

This definition has two major advantages: it is consistent with the main reason for leaving the home-place and allows for a symmetrization of the matrices of movements for each main purpose, which is important when the model is used for forecasting as matrices are generally symmetries within the whole four-step chain.

It was thus necessary to estimate the maximum number of trips for the period of peak demand. For transit planning, modeling just the morning peak was preferred since the maximum intensity of the morning rush hour is close to that of the evening, and morning traffic is more homogeneous in terms of trip purpose. Trips to work and school predominate and the duration of the rush hour is relatively constant.

In contrast, only the evening peak period was typically used for highway and road planning, as the evening rush hour period has been growing and the share of work/school trips declining in favor of shopping, recreation, and other personal trips. Evolving concerns of planning and socioeconomic evaluation has increased the need for modeling the entire travel day, and even trips occurring on weekends.

Unit of Analysis

In the first modeling studies, trip production and trip attraction relations were established at the TAZ level. This approach was limited because it was possible to introduce only a few (one or two) explanatory variables and because of the challenges of using the modifiable areal unit problem (MAUP) for spatial analysis. Today, trip generation relations are rather established at the household or person level, and then the results are aggregated across TAZ. The first argument in favor of modeling at the household level is that some of the trips are related to the maintenance and usual "functioning" of the household and that these trips are managed collectively at the household level. The second concerns the allocation of resources in terms of income and car ownership, which also takes place at the household level. The third is that models at the individual level have specific problems related to a higher proportion of units of analysis that do not travel.

The benefits usually attributed to modeling trip generation at the person level include the fact that, intuitively, trips are made by individuals, not households or areas. The analysis at the individual level can be undertaken from surveys of individuals (rather than households), which reduces the sample size (in terms of number of individuals to sample) needed to obtain similar levels of statistical accuracy. It also allows the use of telephone or Web surveys, which are often made on an individual basis. It is also possible to include household characteristics among the variables characterizing the individual. Furthermore, in the context of forecasting, some demographic changes are easier to model at the level of the individual household.

Studies comparing the explanatory performance of household- and person-level models suggest that both estimate trip ends at the zonal level with similar accuracy, slightly favorable to the individual-level models. The inclusion of variables related to the household in the individual-level approach gives significantly better results during calibration, but this improvement does not necessarily translate into improved forecasting performance. Some studies have shown that the household-level approach can yield slightly better results in forecasting. Moreover, as most studies at the person level actually use data from household surveys, the assumption of independence of observations usually implied by the models (especially regression

models) might not hold. The choice of the unit of analysis must therefore depend on data availability and data analysis even if the individual level is generally preferred.

Cross-Classification Methods and Trip Rates

Cross-classification analysis (CCA) is the modeling method generally accepted as the simplest and therefore the most commonly used, particularly in the American context. It consists of partitioning the sample of households or persons using one or more socioeconomic variables. It is assumed that the groups thus obtained are relatively homogeneous within each category and quite different from one category to another, in terms of trip-making behavior.

The definition of trip rates is closely related to CCA. Trip rates correspond to the average number of trips per household or person calculated for each population segment. The nonparametric nature of the method allows some flexibility in the choice of explanatory variables as it is not necessary to assume a particular form for the relationship between these and the dependent variable.

The main limitation of the method lies in the requirement of a certain number of observations for each category. The analyst is confronted with a trade-off in which increasing the number of categories results in a greater homogeneity of these, but it also leads, for a given population size, to a reduced size of each class and therefore to less robust coefficients (trip rates). Moreover, the choice of variables for the definition of classes does not always lead to resulting groups having similar sizes.

In order to address some of the shortcomings of CCA, alternative methods have been developed. The best-known of these is multiple classification analysis (MCA). MCA is an alternative method used for defining classes and trip rates. For illustration, it is useful to present the case of two independent explanatory variables. First, an average number of trips per household or person for the entire sample is established (a "grand mean").

Subsequently, using the table of trip rates resulting from the CCA of the two independent variables, a mean trip rate for each row and column of the table is calculated. Then the difference between the grand mean and the mean trip rates for each row and column is calculated. Finally, the new trip rate for each cell is defined by adding to the grand mean

the difference with the corresponding row and column. This procedure limits the problems arising from having too few observations in one particular cell of the CCA array.

MCA itself has, however, a number of shortcomings. For instance, the trip rates obtained are different from those obtained with conventional CCA for all the cells. Moreover, some trip rates might have a negative sign and the usual correction applied is to manually give these a value of zero. This is sometimes problematic as CCA might assign a positive value to the same cells.

Regression Methods

Regression methods have been widely used in transport modeling and are still very common for trip generation models. The core of these methods is that they establish a linear relationship between one or several independent variables and the number of trips (or some transformation of the number of trips) for a given unit of observation (zone, household, person, etc.). Regression methods may vary then by the unit of analysis (which is similar to cross-classification methods) but also by type of model.

The most commonly used method is multiple regression by ordinary least squares (OLS). In this method, the number of trips per unit of analysis, conditionally to the values of the different explanatory variables selected, is supposed to be identical, independent and normally distributed (this is also known as the iid normal errors hypothesis) and the explanatory variables are supposed to be independent (i.e., not correlated).

The main advantage of this method is that continuous and discrete explanatory variables can be used. Its major drawbacks have been extensively described in econometrics textbooks. The relation between the variable to be explained and the explanatory variables is linear and only linear, which eliminates other types of correlation. Regression results are less robust when explanatory variables are correlated among them. The iid normal errors hypothesis is not always observed, which leads to less robust estimates. This method struggles in the presence of units of observation (households or persons) that do not go out of their homes.

In order to deal with some of the limits of OLS, other regression methods are used. These are often

called generalized linear models (GLM). The two main models of this kind that are used are the generalized least squares regression (GLS), which mainly deals with the non-observation of the iid normally distributed errors hypothesis, and the logit models, which allow a higher degree of correlation between explanatory variables and deal better with persons or households with zero trips.

One last type of regression method that is gaining in popularity is the tobit model, which is kind of in-between OLS and logit as it has the simplicity of OLS and the possibility to explicitly deal with persons or households with zero trips.

Toward New Microsimulation Methods Based on Automatic Classification

Traditional trip generation methods (i.e., cross-classification and regression) struggle to take into account a big part of the heterogeneity of urban mobility. The variable to be explained is a number of trips (or a number of a particular unit of measure of movements) and therefore the chaining of activities and, in the case of tours containing non-home-based trips, the main purpose of the tour is usually lost.

Moreover, traditional methods have well-known limitations as pertains to their specification. Regression methods are limited in capturing all the interactions between explanatory variables. Cross-classification techniques allow for a wider treatment of interactions between explanatory variables but they lack an optimal procedure for variable selection.

As computing power has increased, automatic algorithms for segmentation have gained in popularity. Algorithms like CART (classification and regression trees) or CHAID (chi-squared automatic interaction detector) allow for establishing a relation between not only the number of trips but also, for example, the types of tours (where the type of each tour is defined by the sequence of trip purposes it contains) and explanatory variables (continuous and discrete), which are segmented automatically according to their explanatory performance (homogeneity of trip behavior).

Once the segments of population with close mobility profiles have been established, the method can be used for forecasting. It is necessary to generate a synthetic population at the time horizon. For each individual who belongs to a segment of the synthetic population, an individual from the travel

survey belonging to the same sociodemographic segment is randomly chosen and his/her mobility pattern is assigned to the individual of the synthetic population.

The method presents several advantages. It generally allows for more explanatory variables, which therefore generates better performance when taking into account sociodemographic evolution of the population like aging or household structure. The random procedure maintains the diversity of mobility profile among population, which is lost when other methods are used. But like other methods, the main limitation is associated with the hypothesis of behavioral stability among each segment.

Stability of Trip Generation Relations

Given data constraints, trip generation models are usually calibrated with cross-sectional data. For forecasting purposes, the hypothesis is made that the parameters of the models are stable. Research on the subject has shown that while this hypothesis is not too problematic for a forecasting horizon less than 10 years, demographic, societal, and behavioral changes make it difficult to use this hypothesis for a forecast over a longer period.

Trip Reduction Programs

Trip reduction programs are the result of local, state, or regional government requirements aimed at encouraging the use of transportation alternatives to single-occupant vehicle travel. Such options include ridesharing, public transit, bicycling, walking, and telecommuting.

The majority of trip reduction programs focus on work-related commutes and peak travel times. As such, employers tend to be the chief implementers of trip reduction programs. Some ordinances cover travel reduction related to shopping and other personal reason, and therefore may impose requirements on commercial property owners, schools, or other public service organizations as well. In some cases, local governments are required to develop and implement transportation management measures such as park-and-ride lots, high occupancy vehicle (HOV) lanes, and shuttle services to support trip reduction mandates.

The main goals of most trip reduction programs are the alleviation of traffic congestion and reduction of associated emissions that contribute to air pollution. Some local, state, and regional governments also use trip reduction programs as interim or supplemental solutions to address financial difficulties tied to adding new transportation capacity for growing demand and to delays in implementing transit improvements.

In addition, public concerns about the social and environmental impacts of transportation capacity expansions and pressure to minimize

traffic implications associated with new development in rapid-growth areas have spurred a move toward trip reduction programs in some areas.

Policy Approaches

Trip reduction policies are based on the specific needs of the local, state, or regional area. There is no single set of policies or master program for all locations or situations; rather, a broad range of trip reduction policies and programs exist. Most trip reduction policies, however, fall under one of the following general types.

Local, state, or regional governments may issue policies that encourage but do not mandate that employers provide commute alternatives information and incentives to their workforce. The same policies may require complementary actions on the part of the government to support the initiatives, such as the creation of an outreach program designed to collaborate with interested employers and their employees. The voluntary nature of compliance with these types of policies means that some employers may not wish to engage. Those that do may cease their participation at any time.

Some trip reduction requirements are included as a bargaining element for negotiations as part of larger policy plans, such as those dealing with rezoning or a major public-private development agreement. The practice enables the trip reduction program to be designed to lessen the negative impacts perceived as potential outcomes of a project. For example, the inclusion of trip reduction elements may allay fears about increased traffic congestion associated with a new development project under consideration.

Trip reduction activities are sometimes included as a requirement for developers or employers who choose to accept government financing or incentives. In these arrangements, the local, state, or regional government gains a willing partner in helping reduce traffic congestion and pollution. Similarly, trip reduction measures are sometimes incorporated into the conditions of approval for new development projects.

For example, a construction permit might require the creation of on-site parking spaces for high-occupancy vehicles or an occupancy permit might stipulate a need for an on-site transportation coordinator. These types of project requirements are negotiated on a case-by-case basis.

Requirements affecting all developments and all employers of a certain size represent another category of trip reduction policies. These policies may require enterprises—usually larger ones—to develop and implement transportation management programs such as ridesharing, flexible work hours, or subsidies for users of alternative commuting methods. The programs may be based on incentives, such as preferential parking for car-pools, or on disincentives, such as the imposition of parking fees for driver-only vehicles. Quantitative performance measures, such as achieving a goal of 25 percent of employees actively engaged in commuting alternatives, also may be a component of required programs.

Governments may issue requirements that sufficient public facilities and services be in place before additional development will be approved. In these situations, the policies may call for developers to implement specific types of facilities and services—such as park-and-ride lots at all major housing developments, sidewalks and bike paths, on-site transit pass sales, or rideshare matching—and to attain certain transportation-related performance standards.

In some cases, trip reduction policies may impose impact fees or benefit assessments as a component in the funding of transportation improvements. The funds may be restricted to capital improvements, such as traffic signal equipment, sidewalk benches, or shuttle buses. Sometimes the funds can be used for operating expenses as well, such as those tied to the provision and administration of rideshare matching services.

Multiple trip reduction policies and approaches are utilized in most jurisdictions as a way to secure the broadest participation possible in transportation management among businesses, developers, and the public.

Factors in Effectiveness

The effectiveness of a trip reduction program relies in large part on the scope of the program—voluntary or mandatory, type and percentage of travel affected, types of trip reduction activities permitted—and how performance is measured.

Local governments may be reluctant to impose trip reduction requirements on existing employers and businesses, especially when those entities claim that the requirements are unnecessary and

burdensome. Enabling employers and businesses to develop their own trip reduction plans generally is considered as a more business-friendly, flexible way to gain acceptance.

However, if participation in a trip reduction program is completely voluntary or if enforcement of mandatory programs is lax, the effectiveness of the program relies largely on whether the plan provides accrued benefits for the businesses that choose to participate. For example, when benefits of participation are perceived as nonexistent or minimal, many organizations will simply choose not to participate, and those that do may fail to put sufficient support behind the program or terminate at the first sign of negative impact. Mandatory trip reduction programs are more likely to achieve the intended results.

A majority of trip reduction programs target a subset of overall travel, such as peak work commute times. If the program applies strictly to certain travel, then logically only a percentage of total travel within a jurisdiction will be affected.

Localities that restrict the reach of their ordinances in such a way typically do so to concentrate their efforts and resources on the best markets for trip reduction. With peak-time commutes, for instance, the trips tend to occur during periods of heavy travel and thus tend to be disproportionate contributors to congestion, emissions, and energy consumption. At the same time, they are the trips that are most easily accommodated by mass transit services and ridesharing.

Most trip reduction programs seek to reduce use of single-occupant vehicles and their associated environmental impacts. However, programs that employ strategies such as flextime or nearby remote parking will produce smaller overall reductions than those that facilitate alternative modes of travel or trip elimination altogether, such as ridesharing or telecommuting. The minimization of single-occupant vehicle use is especially important in areas that are attempting to reduce emissions, fuel consumption, traffic congestion, or parking requirements.

The ways of measuring the success of a trip reduction program vary greatly. Some emphasize procedural measurement, such as whether a plan has been developed or implemented. Others focus on specific outcomes, such as employee participation or automobile usage. The latter provides more

meaningful assessment of the true performance of the program or components within the program.

Adoption Characteristics

In designing an effective trip reduction program, it is important to understand the combined effect of the factors that influence travel choices, such as transportation system characteristics, the physical and chronological distribution of travel activities, socioeconomic characteristics of the affected travelers, economic environment, and local business conditions. For the typical trip reduction program, the key factors to consider are the availability and quality of transportation alternatives, standard travel patterns and trip lengths, employee and employment characteristics, and efforts to support the use of commute alternatives.

The practicality of commute alternatives must be considered from the public's point of view because consumers are the ones who must decide whether to switch travel modes or continue solo commuting. The qualities that commuters generally seek in a viable alternative are whether it can compete with the current travel mode in terms of commute time and cost.

Some commuters may be lured to alternatives by other benefits, such as exercise opportunities or the ability to perform other tasks such as reading while traveling, but these factors typically are not as influential in changing behavior as are issues of time and cost. Public transit can offer a reasonably competitive alternative for many commuters, but service restrictions in suburban areas can be a detriment. Bicycling and walking are viable alternatives in some areas, but ridesharing is by far the most frequently promoted commute alternative in trip reduction programs.

Travel patterns and trip lengths are other factors to consider in assessing commute alternatives. Transportation services are generally better, and the number of potential ridesharing matches larger, for trips to and from major employment centers such as central business districts and large office parks. Longer trips offer the most appeal for ridesharing programs, with carpooling being most effective when participants live at least 20 minutes from work. For employees who live within 10 miles of work, bus transit is a realistic travel option. Bicycling and walking are choices for commuters living within three miles of work.

Even when strong alternatives are available, some employees still may not be willing to change their travel habits. The most likely takers for commute alternatives are usually found among employees who are new to a company, new to a location, or have recently moved residences. Those who come from moderate-income households, follow a fixed work schedule, and do not have a guaranteed, free and convenient parking space are also prime candidates. It is much more difficult to reduce single-occupant commuting activities among employees who have been using that method for an extended period of time, are high wage earners, work irregular hours, or are provided free or inexpensive reserved parking.

For those who need a car to meet personal obligations on the way to or from work, such as dropping children off at school or banking, some employers may be able to offer services to offset those needs. For example, some larger employers provide services such as convenience grocers, dry cleaners, banks, and child care. Larger employers are usually better positioned to provide shuttle services, in-house ride-share matches, and similar support services.

Policies and programs that could bolster trip reduction programs include enabling employers to be reimbursed for subsidies for commute alternatives through their company expense accounts and retracting the ability for employees to “expense” parking costs; taxing employees for employer-provided parking and offering greater deductions for utilization of commute alternatives; and providing HOV lanes for buses, carpools, and vanpools and offering preferential parking for pool vehicles in public facilities.

Potential Impact

Realistic targets for trip reduction programs range from a 5 percent to 10 percent reduction in single-occupancy vehicle trips. Larger reductions in peak-period trips can be generated if alternative work hours are permitted and the peak travel time in the area is short. Larger reductions also may be possible if trip elimination strategies such as telecommuting are promoted. Percentage reductions will likely stabilize after initial start-up, so objectives for the trip reduction programs should be revised periodically to ensure they remain as realistic as possible.

While trip reduction programs may help a community remain within certain traffic limits, it is unlikely that the typical trip reduction program

will have a broad-enough reach to substantially alleviate existing congestion. A more realistic objective might be the prevention of further deterioration of traffic conditions in the face of new growth and development.

In terms of reducing emissions, the extent to which trip reduction programs can help depends on their effectiveness in changing modes of commute and on the extent to which they shift travel to less congested periods, when emissions per mile would likely be lower due to fewer stops, starts, and delays.

Implementation of mandated trip reduction programs can be difficult for smaller employers and certain types of businesses, such as those that require a significant number of employees to have a vehicle for their work. Some of those programs require significant commitments of personnel and funding, and demand a great deal of time and resources for maintenance, monitoring, and enforcement.

Triple Convergence

Traffic congestion during peak traffic hours is ubiquitously present in almost all metropolitan areas. Despite numerous supply-side interventions (e.g.,

building additional expressway lanes, major arterial streets, and expressways), most metropolitan areas continue to remain congested during peak traffic hours. The principle of triple convergence, first posited by Anthony Downs, explains the persistence of congestion on limited-access expressways (also called freeways) during peak traffic hours.

According to the principle of triple convergence, traffic congestion on freeways during peak hours represents a rough state of equilibrium in which freeways do not offer any travel time advantage over alternative routes. Any freeway capacity enhancement is likely to relieve traffic congestion only temporarily. The freeway will eventually become congested again, and the system will arrive at another equilibrium.

The rationale behind the principle of triple convergence is straightforward. Individuals, as rational decision makers, try to optimize their travel costs. Travel cost has two components: time and money. Different travel modes impose different costs: public transit often costs less than driving in monetary terms, but public transit is usually slower than driving. Hence, depending on how much they value their time, individuals choose different travel modes (public transit versus personal vehicle).

If the time it takes to reach a destination by driving is similar to that of traveling by public transit, individuals may be indifferent to the time cost. Other factors such as monetary cost and/or convenience then become more important determinants of mode choice. By the same reasoning, drivers always prefer the fastest route because it imposes the lowest time cost, all else being equal.

Most automobile drivers choose to take the quickest route to their destination, one that is direct, has highest speed, and is least encumbered with obstacles such as traffic signals and stop signs. Except for trips of a very short distance, in most cases this route includes a freeway. Drivers converge on the freeway from various access points until the freeway is loaded with a much higher number of vehicles than it could carry at an optimum speed—that is, it becomes congested and does not offer any travel time advantage over the alternative routes.

It follows that the commuters could reach their destinations using alternative routes (such as surface streets) in as much time as it would take using the freeway. However, despite the congestion,

many commuters continue to drive on the freeway out of habit.

Congestion on the freeway continues to increase to the extent that the freeway route actually becomes slower than the alternative routes. This prompts some drivers to switch to the alternative routes that are now faster than the congested freeway. Eventually, the surface street routes also slow down as a result of increased traffic volume. This process continues until none of the routes offer any advantage over the alternatives, and the transport network is in a state of rough equilibrium.

During the equilibrium, traffic moves at below-optimal speeds on any given freeway or major arterial street. Despite severe congestion, the freeways still carry more vehicles per hour than the surface streets, simply because they have a much larger capacity.

If the capacity of any congested freeway were to be remarkably increased, say by building additional lanes, congestion on the freeway would be reduced and traffic speeds would rise. Driving on the freeway rather than on alternative routes would once again become more advantageous. This would prompt drivers to begin converging on the freeway in the following three ways (hence the term *triple convergence*):

1. *Spatial convergence*: Commuters who were previously driving on an alternative route start using the freeway
2. *Time convergence*: Commuters who were avoiding congestion by traveling before or after peak hours start traveling during peak hours
3. *Mode convergence*: Commuters who were taking public transit during congestion again start driving to work

This triple convergence continues until the freeway becomes congested again and the transport network reaches another equilibrium. Traffic speeds once again drop to levels much lower than the optimum speed, and vehicles are almost crawling on freeways and streets.

Note that any intervention that leads to increased capacity of the transportation network will lead to triple convergence. Even providing a new rail transit service or augmenting an existing one may not relieve peak-hour traffic congestion. Provision of additional

rail transit service would likely prompt some drivers to forgo driving to work and start taking public transit, particularly if travel times in both driving and public transit are similar. This would create room on freeways once again, triggering triple convergence.

Policy Implications

The principle of triple convergence establishes that capacity expansion of freeways, or building additional road capacity anywhere, will not mitigate traffic congestion permanently. Indeed, it is impossible to eliminate peak-hour congestion from freeways and major arterials by building additional capacity unless the capacity of those roads is increased to the extent that they can carry every single commuter simultaneously at the peak minute. This is quite obviously an unreasonable and unrealistic solution. Although adding roadway capacity does not mitigate traffic congestion permanently, it still produces some social benefits. For example, all else being equal, the duration of the peak traffic congestion is likely to become shorter with additional roadway capacity.

Anecdotal evidence tends to support the principle of triple convergence. Traffic congestion has remained persistent in all major cities throughout the world despite substantial enhancement of the transportation network over the past century. Even substantial investment in rail transit infrastructure in several major metropolitan areas has not reduced traffic congestion.

Indeed, some cities with the world's largest public transit infrastructure are also the cities where traffic congestion is most severe—for example, London, Hong Kong, and Seoul. In the United States, several rail transit systems have been built to address traffic congestion, including the Bay Area Rapid Transit (BART) system in San Francisco, California, and the Metropolitan Atlanta Rapid Transit Authority (MARTA) system in Atlanta, Georgia. However, there is no reliable empirical evidence that traffic congestion has actually lessened in those cities as a result of their investment in rail transit.

This discussion suggests that reduction in freeway congestion—due to any intervention—is not permanent because triple convergence will recreate congestion on freeways. However, one strategy that is not likely to lead to triple convergence, and that therefore would reduce traffic congestion in the long term, is to increase driving costs on freeways

through road pricing. This could be done in two ways: (1) as a fixed toll amount irrespective of the time of day or traffic volumes on the freeway, and (2) as congestion pricing where tolls vary, typically being higher during the peak hours and lower during off-peak hours.

Appropriate road pricing would increase the cost of driving on freeways to the extent that triple convergence would not be generated. Indeed, it may produce the opposite effect: triple divergence. In triple divergence, some drivers take alternate routes (spatial divergence), some drivers start using public transit (mode divergence), and some drivers change their commute times to avoid the rush hour (time divergence).

Trolleybuses

A trolleybus or trolleycoach is a hybrid between a bus and a streetcar. Like a bus, it runs on rubber tires and is steered by the driver. Like a streetcar, it has trolley poles on the roof that run along two wires suspended above the road, supplying the electricity to power the motor and operate the trolleybus.

The first trolleybuses began operating in 1905 and were seen as a low-cost alternative to streetcars or trams, because they could use the same power supply but without the need for expensive tracks.

At that time, the gasoline-powered bus was in its infancy and fuel was expensive to obtain. There was another detriment, too: The state of roads at the time was poor and the first trolleybuses ran on solid tires, which did not give a comfortable ride—certainly nowhere near as comfortable as a tram. So for 20 years, trolleybuses were a curiosity that was not taken up further.

The impetus that led to the rapid development and uptake of trolleybuses was twofold. First, the first generation of streetcars was wearing out in the 1930s, needing to be replaced. The second reason was the development of motorbus technology, and especially the pneumatic tire, which gave a smoother ride, even on rough road surfaces. This allowed less busy streetcar lines to be converted to trolleybus operation, retaining the capital investment in the power supply system and providing new vehicles at a lower cost than that for replacement streetcars.

There were, however, several downsides. First, even though trolleybuses were lighter than the trams they replaced, they used more electricity because of the much higher rolling resistance of rubber tires on tarmac roads, compared to streetcar steel wheels on steel rails. Substations needed to be reinforced to provide the extra power. The second operational downside was that as the driver could steer the trolleybus over the whole road, for example, to overtake a parked car, this meant the trolley poles were more prone to de-wire and bring the service to a halt while the operator retrieved the poles.

Some cities went for wholesale replacement of trams by trolleybuses. One example was London, where from 1935 to 1940 half of the tram network was replaced by trolleybuses, creating the largest system in the world. Trolleybuses in London were abandoned in 1962, replaced by diesel power when oil was cheap. As in other British cities, London's trolleybuses were double decked with virtually all passengers seated, and a roving conductor collect fares based on the length of journey made. Today there are 358 trolleybus systems worldwide, most in former or presently communist countries.

Bus Versus Tram Systems

The main differences between bus and tram systems is that buses can be steered anywhere on a road, even to overtake a broken-down bus, whereas

a tram has predetermined tracks and cannot run anywhere else in the road.

Proponents and detractors claim the “flexible” bus can be diverted to avoid problems or extended to serve new areas in a city. A trolleybus can obviously do the first, but not the second, without capital investment in overhead cables and electricity substations to supply power. Recently, however, a new generation of trolleybuses has been developed that has small diesel engines and so can operate off the overhead wires for short distances and at reduced speed.

The main problem with buses is that as no two drivers are the same, and often, because of parked vehicles, buses cannot always pull up exactly at the roadside to provide safe and convenient boarding for passengers with physical or mobility impairments. In contrast, trams can always dock at the same place against the stop platform, making safe boarding and alighting for all passengers automatic at every station. The predetermined trackage for trams also means that passengers have smoother rides with fewer jerks than buses.

Market Perception

Ride quality differences between buses and trams mean that potential passengers can differentiate between buses and trolleybuses, on the one hand, and streetcars and other rail systems, on the other. Even where attempts have been made to provide a pseudo tramway service with trolleybuses, for example by using busways, this is unlikely to entice habitual car users.

At the final stage of this development are guided trolleybuses with tracks like trams (for example, the TVR system adopted by Caen in France). Recently, Caen decided to scrap the TVR and replace it with a tramway, claiming it would have been cheaper in the first place. The TVR running on the same part of the road continuously required expensive and regular repairs. The TVR vehicles were expensive to maintain, being proprietary equipment, and had very high power consumption because of the rubber tires.

Many trolleybus systems have replaced earlier tram or streetcar lines, sometimes extended to serve a new suburb, but always with slightly different terminal arrangements. While trams can run in either direction and so only need a crossover between tracks, trolleybuses are unidirectional and

The guided light transit in Caen, France, is an electrically powered guided trolleybus. There are 24 three-section vehicles, guided by a central nonsupporting rail. The network serves a total of 34 stops and a full 40 percent of public transport trips.

require a turning circle at termini or where several routes share the same terminus, and parallel wired lines to allow overtaking.

The majority of the cities that operate trolleybuses today have low levels of car ownership. Should they reach the levels of more developed countries, it is likely that these trolleybus systems will be abandoned, as they have been in most of North America and western Europe. In some ways, trolleybuses represent the worst of both worlds, the poor ride quality and poor image of buses, and an expensive infrastructure to operate.

More Recent Developments

Like diesel buses, trolleybuses have gotten bigger through the use of a trailer section articulated to the main vehicle to create a single vehicle 60 feet (618 meters) long, and capable of carrying 120 passengers, although most of these will be standing.

There are some examples of vehicles with two trailer sections that together make the bus 79 feet long (24 meters), with a capacity of 150 passengers. Such long vehicles have special requirements, especially pulling into and out of stops at the roadside, because the trailing sections do not follow exactly the same path as the front sections and require a very wide "swept path" on curves. This presents

special problems at terminals, where the articulated trolleybuses turn around to start the return journey.

Operation and Infrastructure

Although trolleybuses do not require tracks installed in the road pavement, the overhead line (OHL) is much more complicated for buses than it is for streetcars or trams. For trams, the overhead line is typically electrified at 500 volts to 750 volts direct current (DC), so that different lines can cross each other without any electrical difficulty.

For trolley buses, there are two wires for each direction. One wire will be DC positive and the other DC negative. This means that at junctions, OHL crossings have to be carefully insulated to prevent short circuits that can result in power failures. This is particularly important to prevent a passing trolley head from creating an arc between positive and negative lines, which can damage and weaken the wire and potentially cause a short circuit. Added to this are the dangers of weather. Rain and snow conduct electricity and can cause arcing between positive and negative lines at OHL crossings.

Trolleybus substations that supply electricity to the OHL also have to be provided, and these can be large, depending on the number of vehicles operating in the section at any one time and the power drawn by each. Similarly, the cable connections between the substation and OHL have to be fully insulated to prevent the possibility of short circuits.

Historically, a trolleybus OHL is divided into electrical sections about one-half mile (one kilometer) long. This allows a section to be isolated in the case of a local emergency (for example, a fire in a building on the side of the trolleybus route) and allow firefighters to put up ladders without fear of electrocution.

Trolleybuses were the first electrical transit vehicles to have power regeneration during braking. That regenerated power ideally needs to be used by accelerating trolleybuses in the vicinity. If this is not the case, then the voltage in the OHL can rise to dangerous levels, threatening to break down cable insulation. This led in the 1930s to the invention of the "Hastings coupler," which effectively turned the whole trolleybus OHL system into a single power network, or "ring main." The Hastings coupler is designed to isolate adjacent power sections if the voltage difference on either side becomes too great, for example, if there is a short circuit in one section

and a regenerating trolleybus in the adjacent. At other times, trolleybuses draw power from whichever substation has available capacity, and regenerated power is distributed to trolleybuses on the network.

The major negative side of trolleybuses is the complex of wires in the sky, which can be considered visual pollution. There are ways to make OHL aesthetically more pleasing and less obtrusive. One of these is to support the OHL by span wires fixed to buildings along the road. This avoids the need to have poles along the side of the street, which can create a vision of a forest of poles. Second, the method of attaching the OHL to the span wires can be by simple insulators, thus avoiding a juxtaposition of wires in the sky.

There are people who claim to find OHL along city streets visually offensive, period. One such group campaigned in San Francisco to scrap the trolley coaches to get rid of the OHL. There was a referendum, with the question "OHL or diesel bus fumes?" People voted overwhelmingly in the referendum to retain the trolley coaches.

Network Structure

Because of the complexity of the OHL infrastructure, trolleybus networks tend to be much simpler than flexible buses. This means that network scheduling and driver timekeepers are very important to running a reliable system. This is because trolleybuses cannot pass one another.

Indeed, there are examples from the United Kingdom when trolleybuses were converted to diesel buses and service reliability deteriorated markedly, much to the annoyance of passengers, often providing them with another reason to buy a car and desert transit.

Against this, there are several important environmental advantages to trolleybuses compared to diesel. First, trolleybuses are much quieter in operation, so they can run in streets where diesel buses would create a noise nuisance. In some cities where traffic noise is loud, trolleybuses often have a little chain dangling from the front to create a tinkling sound that can be heard above the lower frequency traffic noise to warn pedestrians and drivers of an approaching trolleybus.

Second, trolleybuses emit no fumes, toxic or otherwise, in city streets, so they can operate in densely developed areas where air quality would otherwise

be a problem. Some cities have implemented a policy of electric transit only in the city center as a public health measure.

Because trolleybuses can accelerate and brake more quickly and smoothly than diesel buses, fewer are needed to provide the same level of service and passenger capacity. Fewer large vehicles have a benefit for road traffic by helping reduce congestion and pollution, provided complementary traffic management measures are implemented to maintain traffic volumes at a steady flow state.

Interchange Stations

Trolleybuses, like buses, are unidirectional, so the provisions required at interchange stations are more complex and land hungry than they are for trams or streetcars. This may not be a problem if the air rights over the interchange are used for commercial or residential development. For trolleybuses, unlike diesel buses, no special ventilation is needed at interchange stations, since no toxic fumes are emitted. In all other respects, interchange stations for trolleybuses have the same or very similar requirements to other transit interchanges.

Walk and Ride

By definition, trolleybus services will operate on urban roads, and most passengers will walk to the bus stop to get on and walk from the stop at the destination, unless it is an interchange and the journey continues on another transit mode, for example, a subway.

Siting trolleybus stops might seem to be an easy planning exercise. Just plant a pole at the roadside, and trolleybuses will stop to pick up passengers. The science of spacing and locating trolleybus stops is well advanced and balances the theoretical with the practical. The aim of siting trolleybus stops is to attract the largest number of passengers by providing the shortest possible travel times consistent with economical operation. In addition, trolleybus stops need to be located where it is safe to stop and start the vehicle, and practical to pull in and out of the traffic stream.

Some cities make this safety part easier by having continuous or nearly continuous bus lanes along the side of the road, from which other vehicles are excluded. If the rest of the road is congested, then trolleybuses will run at the roadside, faster than the rest of the traffic stream.

The key, however, is the dovetailing of trolleybus stops with land use development. This requires knowledge of where people live and to where they want to travel for work, shopping, leisure, and the other activities that are part of life. Knowing where people live is relatively easy, but unless a full transport study is undertaken, determining journey destinations is more difficult.

Routes that have a mixture of compulsory and request stops can be difficult to schedule. There will be a maximum running time needed, if all request stops are made, and a minimum when none are. Fortunately, computer simulation indicates there is a simple solution to this problem: that is to use the average running time, and to make some of the busiest compulsory stops timing points. Should a trolleybus be running early, as when none of the preceding request stops have been made, the driver waits a short while at the timing point to get back on schedule. If the driver is late at the timing point, the trolleybus will depart immediately on the basis that the probability of stopping at all request stops ahead will be small.

By this means, trolleybuses can be kept evenly spaced, so that convoys do not occur. Convoys cause considerable annoyance to passengers when they see three vehicles pass by, and then a very long gap until the next trolleybus arrives. Here the key is maintaining a high level of reliability and even frequency, characteristics that passengers value and without which there will be a strong incentive to quit transit use.

Truck Drivers, Labor Issues of

The road network serves all the places of production and consumption. Its wide-reaching and flexible nature and its key role in the circulation of freight make it extremely important to global trade, particularly within large urban areas. However, it would cease to exist without the work of those in charge of transporting the goods. Indeed, next to nonmobile handling agents, truck drivers—or truckers in North America, truckies in Australia and New Zealand, and lorry drivers in the United Kingdom (UK)—make up the most important working population in the haulage system. In the United States, the Bureau of Labor Statistics estimated their total number at 2,867,400 in 2010.

Following an overview of the key regulatory features governing truck driving, this entry discusses the tensions that arise from the distinction between driving time and working time and from the social relationships that characterize this profession highly dominated by men. Finally, some perspectives will be drawn in view of the drive toward market deregulation.

In most countries of the developed world, commercial driver's licenses (CDLs) can be obtained from the age of 18. In North America, the Federal Motor Carrier Safety Administration identifies several categories of drivers (e.g., delivery truck drivers, drivers sales workers and heavy and tractor-trailer truck drivers) who must hold distinctive types of licenses defined by criteria such as the gross vehicle weight rating. Similar regulations are applicable in the European Union, including the requirement to undergo a certified training program every five years.

The main task of a truck driver is to make a journey marked by a series of stops between the shippers (for the pickup) and their clients (for the delivery). However, truck drivers represent a heterogeneous group whose daily experience varies according to the type of journey they make. Depending on the destination and the number, distance, and frequency of stops, the journey may last from several hours up to several days or even weeks. For example, as opposed to local drivers, long-haul drivers may spend long periods away from home. Linemen are the only ones who always make the same journey.

Working time is not limited to driving. Time spent waiting, loading and unloading, dealing with paperwork, and so on must also be taken into account. Drivers have to deal with a multiplicity of people who may not always be available, which prevents them from planning their work schedules ahead. The degree of constraint increases with the frequency of stops. Truck drivers thus seek to anticipate the different stages of their journeys so as to devise alternative strategies to cope with unforeseen situations.

While driving time is subject to a number of rules all over the world, this is not always the case with regard to working time. In the United States, a driver may spend a total of 11 hours behind the wheel during a period of 14 consecutive hours. Since 2013, driving is not permitted if more than 8 hours have passed since the end of the driver's last off-duty or sleeper-berth period of at least 30 minutes.

In the European Union, the daily driving time should not exceed 9 hours (twice a week, this may be extended to 10 hours). After driving for 4.5 hours, a driver must take a break of no less than 45 minutes. The weekly driving time cannot exceed 56 hours, nor can the total driving time during any two consecutive weeks exceed 90 hours.

Truck drivers are engaged in two types of social relationships, which both entail some degree of subordination. The first concerns the classical employment relationship between employees (company drivers or wage earners) and their bosses, and the second relates to the contractual arrangements between business entities, including that between owner-operators and independent workers.

In this type of relationship, the two parties are typically shippers on the one hand, and carriers (or forwarders) on the other. Shippers may be farming, industrial, or business enterprises whose production generates merchandise flows (for provisioning and distribution). Forwarding companies are those in charge of transporting shipments for others (a practice known as transport for hire or reward) as opposed to own-account transport companies that carry their own freight. To reduce their inventory costs, shippers reduce or remove their stocks as quickly as possible. Relying on just-in-time management practices, they thus transfer the time constraints of the production process onto forwarding companies.

However, medium-size or large transport companies also increasingly exert pressure on small forwarders by occasionally acting as charterers. This means that they outsource the transportation of their freight to another forwarder, a smaller company or independent owner-operator. They choose to do so because they may be unable or unwilling to meet a demand that is highly exposed to risks or barely profitable, or simply because of insufficient resources.

Consequently, working conditions vary from one type of truck driver to the next. At own-account companies, the organization of work is integrated into the production. Haulage is an integral part of the process of value creation. At companies based on a transport for hire or reward system, the added value stems from freight storage and delivery being achieved within set times. Fluidity is their main objective, and this is heavily dependent upon the driver's ability to adapt to the organizational patterns of the shippers and clients it connects (opening and closing times of the warehouses, availability of personnel at the shipper's, etc.). This requires adjustments of the driver's working and rest hours.

Before the deregulation of road haulage activities, each driver was allocated the same tractor and enjoyed a high level of autonomy. These arrangements were seen as compensation for the flexibility required by the job. But competitive market pressures have led haulage companies to rationalize their activities. They have made their services more flexible by increasingly disconnecting the truck driver from the tractor. At the same time, geolocation systems and other package tracking tools have reduced the advantages that drivers would derive from remote working. Today, management has direct access to a range of information regarding the truck's itinerary, its stops, and whether it is on schedule. It may not necessarily know all the details about difficulties encountered by the drivers, such as traffic conditions or causes for delays at the shipping/receiving places.

Next to the problems of isolation and long periods being away from home, drivers are exposed to several risks. Research conducted in 1987 in France by Patrick Hamelin has shown that the risk of road accidents is correlated with the duration of the work amplitude (from 14 hours and onward, it is 2.5 times higher than under 10 hours of work) and more precisely the number of hours carried

out, and according to the times at which the drivers are at the wheel (at the end of a normal working day and at night). At the same time, the risk of being involved in an accident is doubled when driving during nighttime hours (between 8 P.M. and 6 A.M.). Risk is also present while working on and around trucks (e.g., slipping, tripping, and falling). Accidents can occur when leaving or entering the cab, loading and unloading, connecting the truck tractor to the trailer, or trailer-top operations at clients' premises.

In addition, truck driving also entails a number of long-term health risks. These include musculoskeletal disorders, cardiovascular diseases, hypertension, and sleep disorders. Time constraints and atypical working hours often lead to unhealthy eating habits such as skipping meals or overreliance on fast food restaurants. Moreover, the combination of poor sleeping conditions and the use of drugs to ward off tiredness can lead to hypertension. Finally, constant mobility impedes access to appropriate health care in countries that have failed to develop services for these types of road users.

Since 2010, cabotage, defined by the European Commission as the "national carriage of goods for hire or reward carried out by non-resident haulers on a temporary basis in a host Member State," has been deregulated in Europe, the objective being to reduce the number of journeys made with empty vehicles. But legislative harmony between working and fiscal conditions is still weak. Many national haulage companies fear that they will be outplayed by competitors who enjoy more favorable legislation in their home country.

As a result, truck drivers' working conditions may worsen. Hamelin's research has shown that a way for individual agents to offset the pressure from the institutional and economic environment is to alter their driving behavior. In the UK, they may regularly breach the Highway Code, for example. In fact, this situational behavior is clearly a symptom of a structural phenomenon. Eventually, when the strain and unrest over wages and terms reach a climax, truck drivers resort to industrial action, bringing regional (and in some instances, national) economies to a standstill.

Truck Inspections and Vehicle Licensing

Trucks are any vehicles designed to carry cargo, and they are divided into light, medium, and heavy trucks by the federal government for the purpose of regulation. Light trucks include pickup trucks and some vans, minivans, and sport utility vehicles (SUVs), even when such vehicles are used mainly for personal transportation rather than transporting cargo. Heavier trucks require special driver licensing; a commercial driver's license is required to drive any vehicle over 26,000 pounds.

Class A licenses allow the driver to drive combination vehicles, including coupled buses; Class B licenses allow the driver to drive single vehicles over 26,000 pounds or commercial-use combination vehicles under 26,000 pounds; Class C licenses allow the driver to drive vehicles that carry hazardous materials or more than 15 passengers, and in most states are issued as both commercial and noncommercial licenses. (Noncommercial Class C licenses include large campers and buses used for noncommercial purposes, for instance.)

Commercial driver's licenses (CDLs) are required by federal law but are issued by the states, which is why some of the specifics (e.g., going above and beyond the federal requirements) vary from jurisdiction to jurisdiction. CDLs are also accompanied

by specific coded endorsements listing vehicle-specific training, such as that for hazardous materials transport, air brakes, school buses, or plural trailers.

Like all motor vehicles, trucks are also subject to regular inspections. The periodicity and nature of the inspection varies from state to state. Emissions inspections are required annually in all metropolitan areas with air quality below federal standards, according to the Clean Air Act.

Safety inspections for noncommercial vehicles vary widely, with some states requiring them only upon registration or transfer of ownership and others requiring them annually or every other year, but commercial vehicles are generally subject to inspections that are more stringent or more frequent. In Hawai'i, for instance, vehicles used by emergency personnel, in public transportation or school transportation, or used as rental cars must be inspected every six months, while personal transportation vehicles are inspected only annually. Pennsylvania, too, requires six-month inspections for most commercial vehicles and emergency vehicles.

Because commercial trucks constitute so much of the regular traffic of highways and other routes, and because their sheer size and weight increases the severity of any accident in which they are involved, licensing to ensure competent drivers and inspections to ensure safe vehicles are two measures to reduce the likelihood of accidents. Other measures include restricting truck travel to designated areas; in 15 states, trucks are restricted to certain lanes of the highway, for instance.

Several metropolitan areas use truck bans or diversions to restrict access, including Los Angeles, California, and Atlanta, Georgia, and many have specific initiatives aimed at unsafe and illegal habits such as shoulder parking. The trucking industry is regulated at the federal level by the Federal Motor Carrier Safety Administration (FMCSA), an agency within the Department of Transportation. Federal law requires annual inspections of all commercial motor vehicles, but leaves states free to require stricter or more frequent inspections. In combination vehicles (such as a truck cab and trailer), the inspection must be performed on both.

Motor carriers—companies employing semi-truck and bus drivers and maintaining fleets of vehicles—are responsible for ensuring that their fleets are inspected, just as private owners of automobiles are responsible for having their automobiles

inspected. The FMCSA imposes a number of other regulations, including the blood alcohol concentration at which a trucker is considered intoxicated, a daily and weekly limit on hours driven, and the types of roads on which they may drive.

Commercial trucks may be randomly pulled over for a safety inspection, or pulled over for an inspection because the officer—of whatever body is given authority to do so in a particular state—believes the truck may be unsafe. Trucks that undergo a roadside safety inspection have met their annual inspection requirement and need not schedule an inspection for another 12 months (unless the state requires more frequent inspections).

The American Trucking Associations has criticized random inspections as a waste of resources, claiming that they prevent few accidents, but consume valuable transit time. The trucking lobby in general has argued that regulations in the trucking industry blame truckers disproportionately for accidents, without sufficiently educating non-commercial drivers. For instance, the FMCSA tracks the number of accidents in which a given trucker is involved and whose record can be impinged by accidents in which he has no share of the wrongdoing.

Throughout North America, the truck safety officials' group—the Commercial Vehicle Safety Alliance or VSA (which certifies vehicle inspections)—conducts an annual three-day safety crackdown called Roadcheck. Roadcheck is held with the cooperation of the FMCSA, the Pipeline and Hazardous Materials Safety Administration, the Canadian Council of Motor Transport Administrators, Transport Canada, and Mexico's Secretariat of Communications and Transportation.

During Roadcheck, trucks are selected for random safety inspections at about 1,500 locations throughout North America. The inspections vary in comprehensiveness, though usually more than half are Level 1 inspections, the most thorough, involving an inspection of the vehicle, the driver, and the cargo. The CVSA estimates that during Roadcheck, 14 vehicles are inspected every minute by 10,000 certified inspectors. In addition to the inspections, Roadcheck is an opportunity for inspectors to circulate information about new or recent changes in regulations.

Inspectors ensure that the driver's seatbelt is in working order and check the load securement of

cargo, the position and cleanliness of mirrors, and the personal state of the driver (to make sure he does not seem sleep-deprived, for instance). Brakes are checked for missing, loose, or cracked parts; audible air leaks; correct air pressure; functioning laps and tractor protection system; and brake system warning devices. Lighting is inspected for operation, color, position, and visibility. Coupling and safety devices, including chains and rope, are checked. Fuel tanks are examined for loose mounting and leaks, and exhaust systems have their mounting and system components checked, while seams and clamps are examined for excessive carbon depositing.

The frames of the cab and trailers are examined for cracks, fatigue and signs of stress, corrosion, broken springs, and missing parts. Tires and wheels are checked for proper inflation, signs of damage or fatiguing such as cuts or bulges, tread health and groove depth, defects in the sidewalls, contact with other parts of the vehicle, missing or broken parts, cracked or bent rims, damaged lug nuts and stud holes, cracked spokes or web, and lubricant leaks. The suspension is inspected for signs of misalignment, cracked springs, loose shackles, cracked or loose bolts, and axle misalignment. The steering wheel is examined by manually turning it to confirm that the tires pivot, with the lash measured and compared against the acceptable level.

Trucks must also be licensed or registered with the proper agency, as with any other street vehicle. Departments of Motor Vehicles (DMVs) are responsible for vehicle registration at the state level and requirements vary considerably. For example, California requires some form of California registration for every commercial vehicle on a California highway, which therefore requires interstate drivers to obtain a registration or trip permit (generally good for four days, but longer permits may be applied for) prior to entering the state.

Several private companies offer these and they are also available from the DMV and at truck stops. Companies operating fleets that enter California register their business with the state through the Unified Carrier Registration system introduced in 2007, and pay a fee based on the size of the fleet. Any company operating commercial vehicles that either operate interstate or transport passengers also registers with the Federal Motor Carrier Safety Administration and is assigned a U.S.

Department of Transportation (USDOT) number as an identifier. Some states require the USDOT number as well.

Trucking, Computer Monitoring Systems and

In order to comply with federal and state regulations, many owners and managers of small trucking companies, as well as those of larger fleets, have invested in computer monitoring systems for their vehicles. Most of the monitoring systems on the market today provide benefits well beyond basic compliance with the law. Vehicle tracking technology makes it possible for transportation managers of municipal, commercial, military, and private fleets to collect and interpret data on their trucks and driver behavior. Information on location, speed, fuel use, extended idling, route taken, and unauthorized use, among other driving aspects, can be continually monitored.

The Department of Transportation and Federal Motor Carrier Safety Administration (FMCSA) enforce compliance with regulations that require all truck drivers to carry a log book recording hours

of work service, including the number of driving hours, resting hours, and the times at which duty changes are carried out. The main purpose of hours of service (HOS) records is to prevent accidents caused by driver fatigue. Compliance with HOS documentation for the FMCSA is built into many of the monitoring systems on the market.

Electronic logbooks with HOS software fulfill government regulations by fully automating the entry, recording, completion, and storage of all required information needed for e-logs, and most commercial trucking companies today run their fleets with computerized monitoring systems. These systems are capable of tracking a variety of data, including weight changes and fuel use in the vehicle.

In collaboration with the trucking industry, the FMCSA has been evaluating a number of onboard safety systems through the U.S. Department of Transportation's Intelligent Transportation System (ITS) program. The monitoring systems that may have the greatest effect on reducing costly and deadly commercial motor vehicle accidents are being investigated further. The types of accidents that account for some of the highest numbers of commercial motor vehicle fatalities and injuries are large truck rollovers, lane departures, and rear-end collisions. Onboard devices may be able to warn drivers in the event of situations that could lead to a collision or accident in time for the driver to take preventative action.

Some of these automatic vehicle monitoring (AVM) technologies include roll stability adviser (RSA), roll stability control (RSC), and electronic stability control (ESC). The first system alerts and advises the driver, while the latter two systems actually intervene in the truck's operations. Rear-end collision avoidance technology includes a forward collision warning system (CWS) and adaptive cruise control (ACC), which both utilize computerized vision-based data acquisition. Adaptive cruise control automatically maintains a safe driving distance relative to the vehicle ahead. Lane departure warning systems (LDWS) monitor vehicle position and movement in the lane of travel, detecting any drift from the norm, and alert the driver.

A Global Positioning System (GPS) receiver is installed in each vehicle along with various sensors, depending on which information is to be collected. For example, a sensor can be placed in the fuel tank(s) to track fuel consumption; this data is collected and transmitted to a central location.

GPS satellites should not be confused with communication satellites used for wireless communications. These are two completely separate satellite networks; GPS satellites are used for location purposes only. Real-time systems then use various wireless networks, typically wireless digital cellular, to communicate the location data. GPS data that is collected in the vehicle, along with any other information collected in the vehicle, is typically sent to a server or central operational area. Fleet managers can then view various data depending on the software they use.

Benefits of Truck/Fleet Monitoring

There are many advantages to using vehicle monitoring systems for trucking fleets. The ability to monitor a fleet anytime and anywhere is integral to successful management. Tracking is commonly used by fleet operators for fleet management functions such as routing, dispatch, onboard information, and security. Tracking capabilities offer visibility over fleets, reducing fuel consumption, automating compliance, and reducing maintenance costs.

With more information available, fleet managers can resolve problems such as excessive fuel use, vehicle depreciation, and error-prone manual logbook reporting by drivers. Cutting fuel costs and unauthorized vehicle use while increasing fuel economy and safety compliance can be achieved by using software that enables fleet managers to assess idling times, harsh-braking events, traffic difficulties, and route mileage, along with possible fuel misuse (such as power takeoff, or PTO) or theft.

Monitoring systems enable managers to control routing situations as they arise by dispatching or reassigning vehicles and drivers to areas where need is greatest. Alerts may be scheduled into systems to manage logistics of geographic or time parameter violations. Driver accountability can improve the productivity and efficiency for trucking companies, as well as overall highway safety. Compliance with federal hours of service (HOS) requirements issued by the U.S. Department of Transportation's Federal Motor Carrier Safety Administration (FMCSA) is built into many of the programs on the market.

Future of Truck Monitoring Systems

One bold idea that has piqued interest internationally is truck platooning. This technology uses convoys of

wireless-linked semi-autonomous trucks, or trucks and cars, in a train led by one commanding vehicle and driver. As an example, the train could include three or four trucks that travel on a highway, all at the same speed and same distance (about 12 feet or 4 meters) apart.

The lead driver, who is specially trained, is in command; the followers are “drones,” in which the drivers may read, watch TV, rest, or perform other tasks. All of the vehicles in a platoon have constant, wireless communication with the other vehicles, and adjustments to speed and distance vary with need. Trailing vehicles are also outfitted with radar and laser to allow them to independently detect obstacles and recognize lane markings.

Tests and demonstrations over the past decade in various parts of the world—Germany, the United States, Sweden, and Japan—have shown that fuel efficiency has improved by as much as 15 percent or more due to vehicle drafting. It is thought that platooning and its associated technology could eventually maximize the number of vehicles on the road, while reducing the number of accidents. One of the most advanced demonstrations was undertaken by the European Union–funded SARTRE (which stands for Safe Road Trains for the Environment) project, funded by Volvo. This project explored the use of mixed-vehicle caravans and covered 6,200 miles (10,000 kilometers) of road.

In February 2013, additional platooning road tests were performed in Tsukuba City, Japan, conducted by researchers from the semi-governmental New Energy and Industrial Technology Development Organization (NEDO). Trucks were equipped with automated steering systems and automatic vehicle-following systems. The trucks exchanged information via an inter-vehicle communications system. Many transportation planners believe that platoon formations may ultimately accommodate the heavy freight volumes that are anticipated in high-density corridors between growing urban and commercial areas.

Trucking, Owner-Operators and

Traditionally, the trucking industry comprises a high proportion of owner-operators. Driving an average of 2 million miles in their careers, owner-operators are self-employed commercial truck drivers or small businesses that operate trucks for transporting goods and materials to manufacturers, businesses, and retailers.

In the United States, the trucking industry can be divided into three categories: company driver, independent contractor/owner-operator, or independent owner-operator. Company drivers, who are hired by a company to drive a company-owned truck, are employees of the company. Owner-operators can be split into two distinct groups, independent contractors and independent owner-operators.

Independent contractor owner-operators own the truck they drive. They are financially responsible for all personal and truck expenses, including fuel and tires. The owner-operator leases onto a company that finds loads for the driver. Essentially, they dedicate their truck, equipment, and driving skill to that company, but maintain a level of self-employment. The owner can refuse a load but cannot take work for any other companies. This type of arrangement provides more flexibility to the owner of the truck and, in addition, is beneficial in securing work and providing a degree of certainty over earnings.

On the other hand, independent owner-operators own at least one truck, but they can also own hundreds or thousands of trucks. An independent owner-operator is classified as a "motor carrier." The independent owner-operator can employ a driver to pull his/her trailer, but the owner has

the responsibility for all aspects of the business, including finding the loads for transportation and staff and maintenance costs. In terms of proportions, the number of independent owner-operators working under their own authority is increasing, although it represents less than half of all owner-operators.

There is some confusion with lease companies over the status of independent contractor owner-operators. This concerns the nature of the legislative duties the company has toward them, which would increase significantly were they considered to be employee drivers and enable the owners to benefit from the protection of basic labor law.

In New Jersey, legislation has been created, which, if passed, would establish penalties for trucking operations in the drayage and parcel delivery business for knowingly misclassifying drivers as independent contractors. This would define the

The trucking industry in the United States transports large quantities of raw materials, finished goods, and works in progress over thousands of miles. This mode of transport is an essential service to the American economy. The owner-operators of these big rigs are represented by the Owner-Operator Independent Drivers Association (OOIDA). The organization actively works to affect state and federal laws regarding the trucking industry.

relationship as employer-employee rather than a contract-based relationship. Many owner-operators oppose this type of measure, arguing that if they wished to work for a particular company as an employee, they would already be doing so, and that it destroys the purpose of owner-operating by lease.

There are also a pair of bills under consideration in Washington State's House of Representatives. HB 1440, which has been approved by the House Finance Committee, presumes an employer-employee relationship exists when companies use independent contractor owner-operators. Consideration by the full house is imminent. To add to this, in March 2013, a Californian court ruled that Port of Long Beach truck drivers working for SeaconLogix, Inc., were employees and not independent contractors.

Over the decades, owner-operators have had to contend with many challenges. The latest, referred to as "the great purge of 2008 and 2009," resulted in a decline in owner-operators of 28 percent. This reduction to the trucking industry was a product of the recession and the lowering demand for products and materials as spending declined.

One researcher has argued that inexperienced or new owner-operators are most susceptible to succumbing to the challenges posed by business and fiscal management and organization. Those who make it through the early years, though, are more business savvy and resilient to change. This stands these owner-operators in good stead for future changes affecting the trucking industry, including increasing fuel prices and equipment costs and increasing haulage demand.

Trucking has been a highly regulated industry since the 19th century, when prices and competition became regulated by the federal government as a means of, at the time, protecting the railroad industry from road haulage competition. The Motor Carrier Act 1935 required all new truckers to apply for a Certificate of Public Convenience and Necessity. Emerging companies found it extremely difficult to get a certificate.

Certified trucking companies were required to file tariffs (rates) with the Interstate Commerce Commission (ICC) before they became effective. These tariffs were then made public. If another trucker, regulated water carrier, or a railroad protested the proposed tariffs, these tariffs were usually suspended and investigated for legality. As the

ICC's grip on trucking companies tightened, those wanting to enter the market found that the easiest way to do so was to buy an existing trucker's certificate.

By the 1970s, this had resulted in a commercial market being created in the certificates that entitled trucks to carry goods on certain routes. These regulatory measures reduced competition, raised prices, reduced productivity, and generally created inefficiencies for carriers, which often were unloaded for the return part of their trip due to lack of authorization for haulage.

Congressional enactment of the Motor Carrier Act (MCA) of 1980 reduced the federal oversight of trucking by the ICC and made it easier for a trucker to secure the necessary certification and authorization to operate. The MCA eliminated many restrictions relating to the commodities that could be carried, the routes that could be used, and the geographical region that could be served. It also encouraged truckers to make independent rate filings with even larger price changes.

The MCA also authorized truckers to price freely within a "zone of reasonableness." This meant that truckers could increase or decrease rates from current levels by 15 percent without challenge. As a result of the partial deregulation, the number of licensed carriers rose sharply while the commercial value of operating rights dropped.

Owner-operators are represented by the Owner-Operator Independent Drivers Association (OOIDA). It is the international trade association representing the interests of independent owner-operators and professional drivers on all issues that affect truckers. Of particular focus to the OOIDA is securing equality and fairness, promoting highway safety and responsibility among all road users, and promoting a high level of efficiency and productivity for all operators. There are more than 150,000 members across all U.S. states and Canada. Collectively, these members own and/or operate more than 240,000 individual heavy-duty trucks and small truck fleets.

The characteristics of owner-operators are surveyed by the OOIDA. The 2012 survey found that the male population dominates the owner-operator segment of truckers, with just 3 percent being female. The average age of owner-operators is 54.

This is consistent with current concerns within the wider trucking industry regarding the forthcoming

shortages of drivers in a recovering commercial market because of the advancing age of drivers and also the work conditions. The level of technology differs between owner-operator groups, with those leased onto a company more likely to have satellite tracking such as Global Positioning System (GPS) for messaging and communication (23 percent) while just five percent of those working under their own authority have this type of technology.

Trucks with a classification of 7 or 8 make up 60 percent of those owned and operated. However, there is a tendency within the owner-operator sector to continue driving the present truck rather than investing in a new truck, mainly as a result of the price of new trucks, which has escalated. There are health and safety, environmental, and efficiency implications in holding onto trucks for a longer time rather than replacing them with newer models that offer more sophisticated technologies, fuel efficiencies, and features such as automatic transmission.

Benefits of owner-operating are largely for the owner and driver. The trucking industry is forecasting a shortage of drivers in the United States of over 110,000 by 2014, citing reasons including long working hours and aging vehicles that demand more driver attention and skill (because, for example, of manual gearboxes and the absence of satellite technologies), and the number of owner-operators is rising in anticipation.

Owner-operation provides independence and self-determination in relation to the choice of loads hauled, the destination of the work undertaken, and the schedule of that work. It is also widely considered to offer greater earning potential and greater resilience.

The disadvantages of owner-operator trucking are that it requires discipline on the part of the owner, business management and organizational skills, and the development of a good image within the sector. All responsibility for marketing, networking, finding loads, and maintaining and servicing the truck, as well as keeping paperwork (including logbooks and invoices) falls to the owner-operator.

The degree of autonomy that owner-operator status offers is an attractive prospect, but it is under threat from legislators seeking to identify independent contractor owner-operators as employees rather than contractors. This is widely rejected by the drivers.

However, the upswing in the global economy is paralleled by increasing numbers of owner-operators functioning with authority. With the volume of road haulage expected to increase consistently over the upcoming years, the future is starting to look bright for motivated and disciplined owner-operators.

Trucking Industry

The trucking industry, also referred to as the transportation or logistics industry, involves the transport and distribution of commercial and industrial goods using commercial motor vehicles (CMVs). It provides an essential service in the majority of economies by transporting materials, equipment, products, and personnel over land.

Since the advent of the automobile, trucks have superseded rail in many countries across the globe as the primary mode for the transportation of goods and materials. The ability of trucks to go where there were no tracks resulted in the favoring of road haulage over rail and water.

Today the significance of the trucking industry in the United States and the role it has in the economy is summarized in the expression: "If you bought it, a truck brought it." In fact, the U.S. trucking industry transports 69.5 percent of all commercial freight. This equates to 11,712 million tons and \$9,075,000 million in value. By comparison, rail is responsible for 10.2 percent of inland haulage activity, and water transport for 8.6 percent, according to 2012 data from the Bureau of Transportation Statistics.

The main reason for the dominance of road haulage is the accessibility and door-to-door service available from the trucking industry, which can make transportation of goods faster, more reliable, convenient, and cheaper (in part because of a reduction in handling).

Rail still plays an important role in transporting bulk quantities of cargo over long distances, but it is the trucking industry that hauls this cargo from the most proximate railroad stop to its ultimate destination. As an industry, trucking is characterized by small businesses, with 93 percent of interstate motor carriers operating 20 trucks or less.

As well as being the predominant mode of inland haulage in the United States, the trucking industry employs 10 million people, which equates to one in every 15 people working in the country in jobs that relate directly to trucking. Within this figure, there are 3.46 million truck drivers working directly for the trucking industry in the United States.

Truck drivers are persons employed as the operators of a CMV. The Federal Motor Carrier Safety Administration (FMCSA) defines a CMV as a single or combination (truck or truck and trailer) vehicle with a gross weight of 10,001 pounds (4,536 kilograms) or more, or a vehicle used to transport hazardous materials in quantities requiring the vehicle to be marked or placarded under the hazardous materials regulations. In order to legally operate CMVs, drivers require a commercial driver's license (CDL). This requires undertaking advanced and specific training on handling, maintaining, and understanding CMVs.

The FMCSA, a division of the U.S. Department of Transportation, regulates the majority of aspects of the trucking industry, with the Federal Highway Administration handling mainly the construction and maintenance of national and state highways. This includes the hours-of-service regulations and rules relating to the safety of interstate commercial driving.

The hours of service (HOS) regulations govern the hours of service of commercial drivers. These rules limit the number of daily and weekly hours truckers may drive (Part 395.3 and 395.5), as well as the roads and highways they may drive upon. These laws are designed to protect the general motoring public by reducing accidents caused by driver fatigue.

The HOS regulations limit driver hours to 11 hours of actual driving within a 14-hour period, after which he/she must rest for 10 hours. The rules do not explicitly require that a driver must sleep. Drivers are required to keep track of driving hours in a logbook, which is a legally defined form.

The logbook contains a grid outlining the 24-hour day broken into 15-minute increments. The driver must specify where and when he/she stopped between driving shifts, what duties were performed, along with the driver's name, truck number, company information, and other information. The driver must present the logbook to the FMCSA for inspection when requested.

Log books may be replaced with electronic on-board recorders or tacographs, which electronically record the driver's hours. Most individual long-haul drivers average from 100,000 to 110,000 miles driving per year. Regional and city drivers average 48,000 miles behind the wheel, according to American Trucking Association data from 2007.

One of the main challenges presently facing the trucking industry in the United States is driver shortage. This is particularly a problem for long-haul trucking, with an estimate of a 110,000 driver shortfall by 2014. Reasons for this shortfall include the demographics of drivers, many of whom are approaching retirement age. Age, coupled with the nature of long-haul driving, such as the long hours and periods away from home, the average earnings in comparison to other industries, and the dangerous nature of the work, no longer make trucking as attractive a career as it once was.

In terms of health and safety in the trucking industry, workers experience the most fatalities of all occupations, accounting for 12 percent of all worker deaths. Approximately two-thirds of fatally injured truckers were involved in highway crashes. Truck drivers also have more nonfatal injuries, including strains and sprains (50 percent), fractures, cuts and lacerations, soreness, and pain.

These types of injuries are often caused by unloading the goods transported or in the maintenance of

the truck. It is not only the drivers who are exposed to risks of harm to health and injury but also occupants in other vehicles (including other truckers), pedestrians, and cyclists.

The Drive to Increase Efficiency

The trucking industry has in recent years fallen victim, along with other industries and sectors, to the economic downturn and recession. Small trucking companies have struggled in difficult times to get business as volumes of cargo slipped along with reduced demand and supply need. This, coupled with rising gasoline prices, has driven many companies to reconsider their business model, vehicle fleet, and systems of operation, and to increase productivity in order to improve their competitiveness.

The need to increase productivity and achieve greater economies of scale in a quest for efficiency and profits has led to a variety of technological developments, all of which offer efficiency and cost savings. Improved fuel efficiency and alternative fuels of vehicles is a result of regulatory requirements on the automotive industry, which is changing the fleet composition.

Likewise, new materials, virtual reality simulators, advanced aerodynamic designs, increased efficiency engines, stability control systems, virtual dashboards, real-time Global Positioning System (GPS) monitoring, efficient routing software, and tire pressure in-cab monitoring may be products of the need to improve safety, but they all have a positive effect on efficiency, although they have an up-front cost implication.

Satellite communication has led to increased communication and productivity within the trucking industry. The drivers communicate with their dispatcher who is normally responsible for determining and informing the driver of pickup and drop-off locations, and GPS satellite navigation units enable drivers to concentrate on the road and dispense with paper maps.

Similarly, digital satellite television allows greater choice of television programs for drivers during their off-duty periods, which may improve the allure of long haul driving. The transfer from manual transmissions, which require greater skill and driver concentration, to automatic transmission, in trucks reduces driver fatigue, improves the lifetime of internal gears, reduces the risk of accidents, and increases fuel efficiency.

These developments have increased the productivity of company operations, saved time and effort of drivers, and provided new, more accessible forms of entertainment to truckers who often spend long periods of time away from home, making long-haul work more appealing. In the future, trucks may drive themselves and deliver their cargo to their destinations and be completely monitored at all times through the use of robotic technologies.

The advent of the Internet has revolutionized the trucking industry. It helps companies explore new business opportunities and advertise their service to a wider, more diverse population, and it also enables increased productivity. Furthermore, conducting business transactions in a virtual environment can produce efficiency savings of around 15 percent in comparison to traditional paper transactions.

The most recent developments in the trucking industry relate to the introduction to market by Cummins, a leading engine manufacturer, of CMVs capable of making long runs on natural gas. The cheap supply of natural gas from shale gas extraction means that the investment in this technology would pay for itself over the midterm, particularly with oil prices continuing to rise. Indeed, estimates suggest that the natural gas engines would save truckers \$1.50 per gallon. Furthermore, natural gas burns cleaner than diesel fuel, reducing emissions.

However, until the network of supporting infrastructure emerges that makes natural gas refueling widespread, adoption of these engines will be sluggish. The Federal Energy Information Administration projected that if enough filling stations were built and economic conditions were right, sales of heavy-duty natural gas vehicles could increase to 275,000 in 2035, equivalent to 34 percent of new vehicle sales, from 860 in 2010.

European Trucking Industry

In the European Union (EU), the trucking industry, referred to as either road haulage or heavy goods transport, bears close resemblance in character and composition to that of the United States. In terms of contribution to inland haulage, according to the 2010 statistics from the European Commission Eurostat, freight moved by road in the EU accounted for 76 percent of all freight transportation. This is a 3 percent increase from 2000.

Rail transport in 2010 accounts for 17 percent, compared to over 19 percent in 2000 (Eurostat).

Some states, namely Cyprus, Iceland, and Malta, rely wholly on the trucking industry for the supply and transportation of goods. However, in Latvia, road haulage accounts for only 26.5 percent of freight movement, as opposed to rail transportation, which dominates freight movement at 73.5 percent.

In most countries in Europe, freight transport mainly consists of private companies, and most of these companies are small, with between 65 percent and over 95 percent of the companies having nine or fewer employees. Of course, there are differences between the European countries. The economic recession has led to a decline in the number of companies in freight transport by road, but those companies remaining are considered to be smarter, leaner, greener, and more resilient to future economic change.

While there is little indication of a decrease in reliance on the trucking industry in favor of other modes of freight transport, it is apparent that the industry is recovering from difficult economic circumstances. In the longer term, the crisis may be considered as a necessary step in the transition toward sustainable transportation.

Trucking companies are starting to realize the business benefits associated with implementing more robust environmental and safety measures. These benefits include reducing staff turnover (retaining industry knowledge and skills), widening markets, improved company image, and greater flexibility to adapt to change.

Indeed, companies such as Procter & Gamble are turning where possible to companies with natural gas trucks in their fleets. As more companies seek to “green” their supply chain and reduce their carbon footprint, the trucking industry needs to ensure they remain attractive and capable of competing with alternate modes of transport.

Trucking Industry, Economics of

The trucking industry is an important part of America’s economic foundation and trucks still transport the most freight in the United States, although the industry encountered hard times in the first decades of the 21st century. According to 2012 U.S. Department of Transportation (USDOT) statistics, the transportation industry comprises more than 10 percent of the approximately \$1.4 trillion U.S. gross domestic product, and 82 percent of the money spent in the United States on transportation is spent in the trucking industry. Truck drivers haul 71 percent of all freight moved throughout the United States.

The Journal of Commerce reported some positive trucking industry indicators after the industry suffered significant losses in freight volume from 2008 to 2009. In 2012 revenue increased in the trucking industry and it enjoyed a spike in demand for both long-haul and regional truckers and was firmly on the road to recovery. Long-haul truckload and regional less-than-truckload carriers found a balance in supply and demand and many abandoned chasing unprofitable freight. In its forecast report “U.S. Freight Transportation Forecast to 2023,” the

American Trucking Association (ATA) predicted that overall freight tonnage is expected to grow by 21 percent by 2023, and revenue is expected to increase by 59 percent during the same period. The report stated that the trucking share of total tonnage will increase by 2 percent to 69.6 percent by 2023. Trucking's share of freight revenue will increase from 80.9 percent to 81.7 percent by 2023. Despite positive signs of recovery, the trucking industry still faces several challenges in 2013 and beyond to sustain and expand its growth, challenges that include deregulation and a shortage of truck drivers.

Trucking Economics

The trucking industry is a cyclical part of the economy made up of companies that use tractor trailers to ship goods to customers, who are mostly commercial businesses. Most trucking companies own and operate the vehicles in their fleets, although some do lease them. They make most of their money with domestic shipments, because overseas transportation requires air or sea shipping. The trucking industry tends to be a barometer of the U.S. economy. During an economic upswing, customers ship more goods, anticipating stronger business conditions, and a decrease in trucking demand could signal the beginning of an economic slump.

Major expenses affecting the profitability of trucking companies include labor costs, fuel, operation expansion, and fleet improvement costs. Labor costs significantly impact earnings in the trucking industry because trucking companies need a substantial roster of qualified drivers and freight handlers. Drivers are often in short supply, increasing competition for qualified drivers and the need for the trucking companies to offer competitive wages and benefits to attract the best employees.

Union and nonunion employees also present difficult economic choices to trucking companies. Some trucking companies employ union workers who have strong negotiating leverage and present the risk of labor strife. Nonunion workers come with lower labor costs but sometimes are not as skilled or dependable. Other major labor-related costs include pension expenses and workers compensation.

Trucking companies must also carefully manage fuel expenses. Lengthy trips, heavy loads, and large engines create high fuel costs for tractor trailers.

Most diesel fuel costs are passed on to customers through surcharges, but if fuel prices rise quickly there can be a lag in recouping related outlays that hurt a trucker's short-term profitability. Most trucking companies rely on surcharges instead of long-term fuel contracts.

Various ways that trucking companies finance operating expansion and fleet improvement include cash flow, common equity, and/or debt, depending on the cost of each source. Sometimes a trucking company may assume a heavy debt burden to complete a merger that may offer greater market coverage. Some trucking companies can build cash reserves over a business cycle, and without any pressing capital investment needs, they can reward investors with a big one-time dividend or stock buyback.

The trucking industry bristles with cutthroat competition, because customers have an array of choices, including privately held carriers and companies outside the industry like air and railroad freight organizations. Trucking companies strive to provide excellent customer service to encourage repeat business and to develop close company-customer relationships. Price competition is also fierce and trucking companies usually operate with narrow profit-loss margins.

Truckload and less-than-truckload companies make up the two primary segments within the trucking industry. Truckload carriers load a trailer with large cargo from one customer, usually in the same truck and usually bound for a single destination. Less-than-truckload companies load a trailer with small amounts of cargos from several different customers bound for different delivery destinations. Trucks carrying less-than-truckload goods may stop at multiple terminals and goods can be transferred from several different trucks before reaching their destination. Both types of trucking companies have an established network of terminals and distribution centers across the country.

Seasons affect the trucking industry, with all trucking companies generally experiencing increased demand during the holiday shopping season. Less-than-truckload companies may experience high demand in the middle of the year because of a decreased need to transport large amounts of the same kind of freight. Business usually slows for both truckload and less-than-truckload during the first half of the year because of weather disruptions.

To retain a competitive edge and satisfy their customers, trucking companies must maintain a large collection of tractors and trailers—sometimes numbering in the thousands—and they must upgrade their fleets often, generally every five years for tractors. Frequent upgrades help curb maintenance expenses, since older vehicles require more upkeep and increasing stringent Federal environmental standards compel trucking companies to buy newer, more efficient trucks. New fleets also help attract better qualified drivers during tight labor markets.

Trucking companies must also adjust fleet sizes to match current economic situations, decreasing the number of trucks in operation during downturns to avoid excess capacity. When the truck supply exceeds the demand, trucks produce less revenue per vehicle and other negative numbers.

Economic Fluctuations

With the advent of paved roads in the 1930s, trucking gained a foundational foothold in the United States economy and the construction of the Interstate highway system in the late 1950s and 1960s solidified the economic importance of trucking. Regulation and containerization also helped shape the trucking industry. Congress passed the Motor Carrier Act in 1935, granting the Interstate Commerce Commission the authority to regulate trucks and drivers involved in interstate commerce by granting operating permits, approving truck routes, and setting tariff rates. Since the tariff rates were the same for all trucking companies, price wars were infrequent.

Congress created the USDOT in 1967, and it has had an important impact on the trucking industry. The USDOT oversees trucking requirements like braking and driver licensing standards, maximum work hours, and the safety fitness of interstate carriers. The Motor Carrier Act of 1980 partly deregulated the trucking industry. The decade after deregulation ushered in fierce competition in the trucking industry, with hundreds of new companies and less civility and more intense competition between the leading trucking companies.

By the end of the 1980s, one-third of the 100 largest trucking companies had gone out of business, destroyed by the fierce competition. Trucking companies found it increasingly difficult to operate with union drivers because union drivers earned at

least 35 percent more money than nonunion drivers. New companies were created to operate with nonunion drivers or independent contractors to reduce operating costs.

The Surface Transportation Act of 1982 set uniform size and weight limits for the nationwide trucking industry, stipulating that trucks using interstate highways could not weigh more than 80,000 pounds. The Carrier Reform Act of 1994 reduced the time for customers to file an overcharge claim. By the end of 1995, additional legislation had essentially deregulated the trucking industry and, because of the changes in federal law that preempted the states from regulating the intrastate activities of interstate carriers, many states either deregulated or significantly eased the economic controls over truckers operating solely within their borders. Congress abolished the Interstate Commerce Commission in 1995 and established the Surface Transportation Board (STB), an independent unit operating within the Department of Transportation. The STB administers the remaining regulatory functions for the trucking industry.

The year 2000 turned out to be an unsettled one for the trucking industry, featuring high fuel prices, battles over U.S. taxes, and plummeting new truck sales, but despite the problems the market created more freight and activity for truckers. The fall of 1999 through the spring of 2000 saw the entire trucking industry face a falling of used-truck prices, threatening to undermine the economic health of the nation's fleets, truck manufacturers, and truck finance companies.

Companies bought up low-mileage and used trucks and tractors to try to avoid buying new trucks with the 2002 engines. A flood of good, low-mileage tractors overwhelmed the market and depressed prices to the lowest levels in years. Under accounting rules, the falling value of their massive investments in equipment left about two-thirds of North American trucking companies nearly bankrupt. Bankruptcy filings were widespread and the equipment issue was even more important than escalating fuel prices and driver shortages.

The U.S. economy again stagnated in 2003, and fuel prices and insurance costs pirated a chunk of profits from trucking's bottom line. According to the Department of Energy, the average price of a gallon of diesel fuel in the United States soared to a new record of \$1.51. In 2003, at least 5,000

trucking firms went out of business, and as the hard economic times pushed trucking fleets out of business, trucking capacity declined. Many fleets sliced their operating ratios, which show a company's expenses as a percentage of its revenue, during the year. Operating ratios indicate profitability with an operating ratio of 100 showing a break-even company. An operating ratio of 85 was the best in the trucking industry. When the economy finally rebounded, trucking fleets raised rates as shippers scrambled to find carriers to move their goods, but mergers and acquisitions were the primary moving force behind changes in the trucking industry during 2003.

New driver hours of service rules took effect on January 4, 2004, which effectively reduced on-duty time for drivers and increased the time a driver had to take off between shifts. Many carriers were forced to increase driver pay to recruit and retain drivers in 2004. Demand for drivers was high and the supply limited. The American Trucking Association reported that in the third quarter of 2004, large truckload line haul driver turnover reached a new all-time high of 121 annualized percent.

In 2005, driver turnover remained high, with less-than-truckload turnover at roughly 40 percent and long-haul package truckload driver turnover running over 100 percent. Bulk liquid driver turnover reached over 60 percent. The driver shortage across the U.S. trucking industry ran over 100,000 in the second quarter of 2005.

In 2006, there was heavy pre-buying of trucks and tractors in anticipation of the new 2007 engines and fuel standards. The 2007 trucks and tractors were costlier and averaged fewer miles per gallon. The national average price of diesel fuel reached \$2.745 per gallon through September 2006.

In 2009, over 3,000 trucking companies, mainly small companies and owner-operators, went out of business. After a modest economic recovery in 2010, truck manufacturing surged during 2011, rising from 49,000 in the first quarter to 77,000 in the fourth quarter. The trend reversed in 2012, beginning near 75,000 in the first quarter and ending the year producing just 55,000 units in the fourth quarter.

Twenty-First-Century Economic Challenges

The challenges that the trucking industry faces in the years ahead include federal regulations like new hours of service rules that, if enforced, could create

capacity strains on trucking. As capacity tightens, companies try to expand their sustainability initiatives and shippers turn to intermodal rail in traditional trucking lanes.

The popularity of rail transportation also will continue to challenge the trucking industry to find alternative environmentally friendly fuel sources that offer cost savings in the long run. Although freight tonnage is expected to increase by 21 percent by 2025, the trucking industry must remain competitive when pricing freight services in order to retain a steady level of business and growth.

A sustained truck driver shortage could present a significant challenge to the industry, if the U.S. economy grows at a greater pace than anticipated. The Department of Labor reported that in February 2013, when retail and manufacturing grew steadily, the trucking industry added 5,700 jobs. When it began to slow in March, trucking companies cut 6,900 positions.

The Commerce Department reported that home sales increased 1.5 percent in the spring of 2013, with high levels of demand pushing property values up. Construction firms building more new homes create a demand for lumber and other building materials that need to be transported across the country by trucking companies.

Trucks

Trucks are road vehicles larger than a car that are designed for hauling heavy, bulky, or numerous items. In Europe, trucks are referred to as commercial vehicles. Truck design varies according to the intended purpose or freight to be carried; trucks are classified as light, medium, heavy, and very heavy.

Many smaller trucks are manufactured as a single vehicle with a cargo container area, such as a pickup truck. Larger trucks may be built as a single unit for a particular purpose (such as a tow truck, tractor, cement truck, or backhoe) or customized around what is called a chassis cab, which is a truck with a cab and a set of rails that can be specialized depending on the apparatus added to the rear (for example, dump truck bed, camper unit, or containers for various uses).

Many heavy trucks, known as tractor trailers or semi-trailer trucks, have two (or more) separate parts, including the towing engine (also called a rig, cab, or tractor) and a trailer, which, once again, is designed for a specific purpose or use (for example, a tank for fluids, large box container for ocean shipping, specialized container for carrying live animals, etc.)

Trucks usually have diesel-powered engines because of the greater demands placed on the engine, and these engine's greater efficiency and longevity. However, gasoline variants are common in smaller trucks, particularly in the United States. Automatic rather than manual gearboxes are becoming increasingly commonplace in trucks operating in the United States, whereas manual transmissions are more popular in other countries.

Trucks are normally built on a ladder frame, referred to as a chassis in Europe. Chassis are constructed of steel symmetrical C-shape beams or tubes linked by cross members to which the running gear, engine, gear box, axles, wheels, steering, body work, and internal fixtures are mounted.

In the United States, trucks are classified by the U.S. Department of Transportation (US DOT), into eight classifications: Groups 1 through 3 are light trucks, Groups 4 through 6 are medium-duty trucks, and Groups 7 and 8 are heavy trucks.

Light trucks, which are the most popular, are frequently used for either private travel or recreational uses. Medium trucks are generally used for short-haul trips, and larger trucks, with their

greater payload, can transport bulky or heavy loads on long-haul journeys.

Each classification sets specific standards for vehicles, such as requiring only a standard driver's license to operate Class 1 through 6 vehicles, while Class 7 (with weights from 26,001 to 33,000 pounds) and Class 8 trucks (33,001 pounds and above) require special skills and a commercial driver's license.

The classification of the truck determines the cost of vehicle registration fees and taxes, and higher categories also require specific inspection and safety standards to be met. The largest trucks generally require more qualified drivers; for this and taxation purposes, trucks are segregated into various classifications based on gross vehicle weight, or the maximum operational weight of the vehicle fully laden with fuel and driver.

In Europe, like the United States, the larger-sized vehicles require greater legislation and attract greater taxation. The size of commercial vehicle an individual can drive is dependent not only upon what driving qualifications the individual has but also on when they took the driving qualifications. This means that individuals having taken the standard car test before 1997 are capable of driving a single unit truck up to 16,500 pounds or a combination truck and trailer up to 18,100 pounds.

For those qualifying to drive after 1997, the limit on truck size they may legally drive without further training is up to 7,700 pounds and 9,350 pounds, respectively.

The 7,700-pound-class, mostly van based, is the most common. The second most popular class of trucks in Europe is the 16,500-pound single-unit truck. Drivers of these vehicles tend to be older and not to have any formal additional driving qualification over and above the standard car license. Truck-and-trailer combinations up to 97,000 pounds are generally the largest truck allowed on most roads in Europe and tend to mainly be used for long-haul transportation.

In Australia, the heavy-duty-truck sector is the most popular, equating to 16 percent of the market. This is followed by the light-truck sector (12 percent of market), comprising vehicles up to 9,920 pounds. The light-truck category requires no further formal driving qualification. Vans dominate in the Australian light-sector market, but single-unit/chassis trucks are also common.

Single-Unit Trucks

Single-unit trucks/chassis cabs, or rigid trucks, are manufactured with the area behind the driver's cab exposed. This allows the vehicle's owner to build or specify from a coachbuilder the body work best suited for the type of cargo the vehicle is intended to carry. Once the body is fitted on these chassis cabs, they are then referred to as "rigids."

In Europe, classification of trucks is governed by European Union (EU) law and national legislation in member states; for example, the Road Vehicle (Construction and Use) Regulations 1986 in the UK. Single-unit trucks (SUTs), referred to as "chassis cabs," come in a number of size and weight combinations. Two-axle commercial vehicles can be up to 39,650 pounds and are generally used for short hauls and urban loads; three-axle vehicles are limited to 57,320 pounds, and four-axle chassis cabs have a maximum weight load of 70,500 pounds and can run up to 40 feet in length.

In recent years, three-axle vehicles have become increasingly common, particularly for medium-distance work, because they offer greater efficiency, with more miles per gallon (mpg) than their counterparts, including semis and articulated vehicles.

In the United States, SUTs are trucks that are used for general hauling over short distances. Trucks with two axles are used in urban areas and have a maximum weight of 40,000 pounds. SUTs with three axles have a maximum weight of 50,000 to 65,000 pounds. SUTs with five or more axles have a maximum weight of 70,000 pounds and are used to carry the heaviest of loads, such as construction and building materials.

Tractor Units

Tractor units, or fifth-wheel trucks, have an exposed chassis to the rear of the driver's cab, but rather than a specific body being bolted on, a coupling link is mounted on the rear chassis that allows a semi-trailer to be attached. A semi-trailer or "semi" is a trailer with its front axle or set of wheels missing because the weight of the trailer is borne by the tractor unit while it is being transported.

Rather than a set of road wheels at the front of the semi, the trailer has a large steel pin, known as the "kingpin," that slots into the coupling link on the tractor unit, taking a large proportion of the trailer's weight and allowing the trailer to pivot from the tractor unit. The chief commercial advantage of the

This road train in Australia is considered one of the world's longest; road trains are especially suited to conditions in Australia. The trailer arrangement is B-double towing two tri-axle trailers. These large road trains are also known as turnpike trains.

semi is that a truck can be used to transport one trailer while another one is being loaded. In addition, in the event of a breakdown, the loaded trailer can be simply attached to another tractor unit to continue its journey.

In both the United States and Europe the tractor and semi is the preferred combination for heavy-load trucks. In the United States and Australia, these trucks follow the car convention of having the engine and hood out front beyond the cab and are known as "conventional trucks." These offer improved ride comfort for truckers because the longer a vehicle's wheelbase, the less choppy the ride, and improved aerodynamics offer greater fuel efficiency over their European counterparts.

These conventional tractor units have a single forward axle with two wheels, and two rear axles with two to four wheels on each axle. This is where the truck garners the name 18-wheeler, because it has a total of 18 wheels, including the trailer. It can haul a variety of different trailers, including flatbed trailers, enclosed trailers, or tanks.

In Europe, heavy-load tractor units are normally three-axle tractor units with a cab-over-engine design often called "forward control." The principal benefit of this, as opposed to a forward axle with a bonnet/hood beyond the cab, is to allow a longer trailer, because the overall vehicle length is limited by law to 54 feet (16.5 meters). In addition, trailer wheels on European semis are single as opposed to

double-wheel axles. These “super singles” reduce rolling resistance, which improves fuel mileage. Typically, these combined tractor-and-semi vehicles have a gross weight of up to 97,000 pounds and are limited to a maximum motorway/freeway speed of 56 mph.

“Road trains,” “turnpike trains,” or tandem trailers consist of more than one semi-trailer or a single-unit vehicle towing a trailer or dolly (that is, a small trailer with fifth wheel to which a semi-trailer is connected). These are the largest trucks on highways, although they are used less often than traditional semis because of their tendency to sway or fishtail, their longer required braking distance, and the fact that the entire load cannot be detached from the towing vehicle when it is towed by a single unit truck.

In Europe, such combinations can be driven on any road (unless stipulated otherwise) up to a maximum length of 61.5 feet (18.75 meters). Their weight remains restricted to a maximum of 97,000 pounds. The largest variants of road trains can be found in Australia, where a relatively spartan rail infrastructure, great spans of distance to cover, and low population density make road trains an ideal transport solution; one large road train is capable of making the journey that would otherwise require several traditional tractors and semis.

Trailer Types Vary by Function

Truck bodies and trailers are products of the different needs they fulfil. Some of the more common trailer types include the following:

- *Dump trucks*: These have a large open topped container that extends upward on a hydraulic arm. This is used to pick up, haul, and easily unload dirt and gravel.
- *Garbage trucks*: These have hydraulic crushing arms that compact waste.
- *Boom trucks*: Designed to lift or elevate an item or person, these trucks have an arm-like crane boom mounting on a bed behind the truck cab. Boom trucks are used by construction workers to build homes and by utility companies to string cable wires.
- *Flatbeds*: These are made up of a chassis fitted with a platform body on which goods are carried. Cargo is secured on the deck with ropes or sheeting
- *Curtain-siders*: These have a fixed, roofed frame with a flexible curtain fixed to both sides of the frame. They are ideal for carrying pallets that require protection from the weather. Curtain-siders provide easy access to the load for efficient loading and unloading, but have less security than box-bodied vehicles.
- *Box bodies*: These trucks are comprised of a rigid body with solid sides and have solid rear-opening doors or roller shutters.
- *Temperature-controlled*: These are box bodies made of insulated material with a refrigerator unit attached. They are designed to carry temperature-sensitive loads such as chilled or frozen products. The cooling unit is powered by either the main engine or a separate engine.
- *Luton peak bodies*: These are box vans with an additional section over the cab for holding any loose cargo or other tools. They are often used for furniture transport and removals.
- *Road tankers*: These have a permanent tank fitted to the chassis for the transportation of liquids, gases, or powders.
- *Teardrop trailers*: Designed with a curve the whole length of the semi-trailer, they can return a 10 percent savings on fuel over a conventional box semi-trailer.

Recent developments, such as the teardrop trailer, have concentrated on increasing fuel efficiency and a lowering of emissions. In Europe, laws on emissions standards for engines adopted in 2011 establish targets for the reduction of emissions from vans and heavier commercial vehicles, mainly through tailpipe emission limits. Similar laws are increasingly taking effect with more stringency and consistency in the United States. Coupled with a compelling business case to reduce emissions of trucks and increase efficiency, this means that greater focus is being placed on how technology can improve truck efficiencies, reduce carbon and other greenhouse gas emissions, and improve road safety, all of which enhance the competitiveness of road haulage in a period of economic transition.

Trucks, Safety Issues and

According to U.S. Department of Transportation (USDOT) statistics, overall traffic fatalities decreased in 2011 for the second consecutive year while truck crash fatalities increased, especially in the truck occupant category, which recorded a 20 percent jump. The Federal Motor Carrier Safety Administration (FMCSA) reported that the estimated 2 million or more tractor-trailers operating in the United States represent 4 percent of all registered vehicles, but they are involved in 8 percent of all fatal collisions each year. These statistics underscore safety issues with large trucks, which pose risks to passenger vehicle occupants and truck drivers themselves. These safety issues that the trucking industry has addressed with varying degrees of success include driver health issues, especially driver fatigue, vehicle conditions, and tandem trailers.

Truck Industry Safety Issues

One of the biggest trucking industry safety issues for the public is traffic tie-ups with the attendant consequences of missed appointments, missed deliveries, missed planes, and people late for work. Truck accidents are a bigger problem to tackle, especially when spill materials have to be cleaned up or towed away. The Insurance Institute for Highway Safety, which has been studying truck accidents for decades, estimated the costs of a single accident—a tanker flipping over while hauling 8,000 gallons of gasoline on part of the Washington, D.C., beltway in May 2011.

Damages, cleanup, police and fire services, and road repairs totaled \$571,789, not to mention the inconvenience for thousands of drivers.

The Insurance Institute for Highway Safety pinpointed 14 proposals to improve truck safety, including requiring anti-lock brakes and discouraging the trend toward larger trucks that began with the 1980 deregulation of trucking. Deregulation inspired a price war that drove down profits and required trucking companies to increase productivity to survive. With increased productivity, the same drivers had to haul larger trailers and heavier cargos.

More than 95 percent of the trailers produced were 45 feet long or less before deregulation, but by 1986 more than one-half were more than 45 feet long and another one-third were the 28-foot-long trailers used in pairs as tandems, according to the Truck Trailer Manufacturers Association. Now the trucking industry trend is triple trailers and Insurance Institute statistics show that tandem trailers are up to three times as likely to be in crashes as other big trucks because of sway and stability problems. The institute is also seeking tougher licensing rules for truckers.

Brakes

Brake Safety Week is part of the Operation Air-brake program jointly operated by the Commercial Vehicle Safety Alliance (CVSA) and the FMCSA and part of an international effort to prevent truck and bus crashes to save lives throughout North America. According to a recent large crash causation study, brakes were a factor in nearly three of 10 commercial motor vehicle (CMV) crashes.

During annual Brake Safety Week inspections in the fall of 2012, the CVSA reported that in September 2012, one out of seven of 21,255 vehicles were placed out of service because of brake issues and brakes have been cited as a factor in 29.4 percent of commercial motor vehicle crashes. Stopping distances for trucks and buses are longer than for passenger cars and they increase significantly with many of the brake violations that are uncovered during the September brake inspections.

Underride Guards

Federal law requires underride guards, metal bars running the width of the trailer and fixed by two posts mounted underneath the tail lights, on nearly all 18-wheeler tractor-trailers. When they work, the

bars prevent a vehicle from sliding underneath the trailer and crushing its passengers during an accident. In a new study, the Insurance Institute for Highway Safety (IIHS) has found that the under-ride steel guards installed on the back of tractor-trailers often buckle and break and even the steel guards meeting federal safety standards can fail in low-speed crashes.

National Highway Traffic Safety Administration (NHTSA) rules, effective in 1998, required lower and wider guards on new trailers, but they did not apply to many of the heavy trucks used on the nation's roads, so the IIHS is petitioning the agency to require stronger underride guards and mandate them for larger trucks and trailers.

Tandem or Twin Trail Trucks

The Surface Transportation Act of 1982 contained a little-known and little-discussed provision that effectively overrode all state laws banning tandem or twin trailer trucks on the highways. Although some states ban tandem rigs on turnpikes and other highways, federal law stipulates that they are permitted on every interstate highway and sections of primary roads that the U.S. secretary of transportation mandates. The trucks and their truckers also must be allowed access to fuel, repair, terminal, food, and lodging facilities, even the ones located in old and congested cities like Philadelphia and Boston.

Opponents of the tandem trailers contend that they are more frequently involved in fatal accidents, with a 1982 NHTSA study determining that in an accident involving a passenger car and a tandem trailer truck, the car passengers are 29 times more likely to be killed than the truck driver. Other critics object to the additional weight that could damage roads as well as endanger travelers, and others point out that although a truck operator is required to apply for permission to haul loads heavier than 80,000 pounds, these permits are easy to obtain and they fear that gross weights may routinely climb to 95,000 pounds and beyond. They say that economically distressed states enforce weight limits loosely and opening up new roads to tandem trailers make, it easy for truckers to dodge state scales.

Driver Health

Truck drivers appear to have the freedom of the open road, but the reality of their occupation is

that their freedom has stringent restrictions. *The International Hazard Data Sheets on Occupations* highlights the occupational hazards that truck drivers face, including the high statistical probability of highway accidents because of their long hours on the road, injuries like sprains and strains from loading and unloading goods on and off the truck, and hauling hazardous material cargoes. The Centers for Disease Control and Prevention and the National Institute for Occupational Safety and Health (NIOSH) recognize that truck drivers are at an increased risk for many specific health problems such as depression, heart attacks, cancer, obesity, sleep apnea, high blood pressure, and diabetes.

In a 2007 study, the *Journal of the American Dietetic Association* estimated that 86 percent of the approximately 3.2 million truck drivers in the United States are overweight or obese for reasons including long work hours and a sedentary lifestyle. Eighty percent of truckers have unhealthy eating patterns because of limited choices of healthy food at truck stops, fast food diners, and vending machines. Irregular snacking and sporadic sleep habits also contribute to their obesity, as do lack of exercise and long work hours and tight deadlines. Truckers often have little or no health insurance and limited access to health care. The Department of Transportation has established Convenient Care Clinics for truckers across the United States, but they are scattered and difficult to find. Health care costs are higher for obese truckers, placing a greater financial demand on the trucking industry. Truckers themselves contribute to their job stress by pushing themselves to the limit to adhere to schedules and neglecting their health on the road. The life expectancy for truck drivers is 61 years, 16 years less than the average.

Fatigue and Hours of Service Rules

Almost 30 percent of commercial truck drivers have a version of sleep apnea, and driver fatigue is a health issue that affects the entire trucking industry. U.S. Department of Transportation surveys reveal that 65 percent of truck drivers report that they often or sometimes feel drowsy while they are driving and nearly half of truck drivers admitted that they had fallen asleep while driving. To complicate the issue, the wages for many truck drivers depend on the miles they drive, and trucking companies also increase their profits when their drivers

cover more miles. This pressure for mileage creates a system that encourages drivers to push past their fatigue limits.

Before the 1980s, few rules establishing the number of hours a truck driver could drive without a rest period existed, and the rules that were on the books were not consistently enforced. Since the 1980s, the federal government has set forth a number of rules addressing the issue of truck driver fatigue in an attempt to make roads safer. The FMCSA established hours of service regulations. These regulations specify how many hours a trucker may drive without taking a rest, how long a driver must rest before driving again, and how many hours a trucker may drive in a week's time. Under the old rules, drivers could work up to 82 hours in seven days, but in 2011, the rules were modified to permit drivers to work up to only 70 hours in seven days. There is an 11-hour per day limit with 10 hours off mandated after the weekly shift. Companies allowing truckers to work beyond 11 hours may be fined up to \$11,000 and individual drivers up to \$2,750, but this law is minimally enforced.

Despite the hours of service rules, the number of tractor-trailer fatality accidents is still climbing, with the National Highway Transportation Safety Administration reporting that in 2011, the number of people killed in large-truck crashes rose 1.9 percent, and the number of truck accident fatalities involving people not riding in the trucks increased 19 percent.

A major shortcoming of the hours of service rules is that drivers themselves report their hours on the road in written logbooks. The majority of drivers are honest, but it takes just one fatigued trucker illegally driving an 18-wheeler to cause a catastrophic accident.

Regulating Trucks and Drivers

In May 2013, the Truck Safety Coalition, safety and labor advocates, and Senator Frank Lautenberg (D-NJ) and Representative James McGovern (D-MA) supported the Safe Highways and Infrastructure Preservation Act (SHIPA), which would freeze existing federal truck size and weight limits, close loopholes that allowed overweight trucks to operate, and establish an enforcement program to ensure accountability. A poll that Lake Research Partners conducted for the Truck Safety

Coalition (TSC) showed that 68 percent of Americans opposed heavier trucks, with 88 percent overwhelmingly opposing paying higher taxes for infrastructure damage from heavier trucks.

Tunnels, Safety and Security Issues in

Tunnels are a cost-effective traffic engineering method allowing roads or railways to traverse difficult terrain such as mountains, waterways, or congested urban areas while mitigating environmental impacts. Tunnels have historically been key components of automobile, mass transit, and train transportation systems. When roadways emerged as the main avenue of transportation of both passengers and commercial goods in the mid-to-late 20th century, tunnel construction and usage increased.

The complex infrastructure and typically heavy usage of tunnels, however, present a number of safety and security issues that must be addressed. Tunnel fires have historically been one of the most severe safety issues, while the potential for terrorist

incidents has recently begun to receive more concern. Other tunnel safety and security issues include hazardous materials transportation, ground collapses, floods, and gas leaks or explosions.

Types of Tunnel Safety and Security Issues

Tunnel safety and security issues arise in all phases of a tunnel's life, from design and construction through maintenance and operation. Tunnels are by their nature confined spaces with one entryway and one exit. Therefore, incidents or accidents that occur within a tunnel have the potential to result in serious structural damage, injury and loss of life, environmental damage, and/or transportation disruptions. Traffic accidents within tunnels, such as the highly publicized crash that claimed the life of England's Princess Diana in 1997, also present unique challenges.

Tunnel safety and security issues begin to be addressed during the planning, design, and construction phases. The fact that tunnels are constructed underground or beneath bodies of water increases the risks and safety needs inherent in construction.

Tunnel construction necessarily involves disturbances to the rock or soil due to excavation, leading to the potential for ground collapse. Water intrusion can result in flooding, weakening of the soil, electrical equipment malfunctions, and other safety concerns. Other workplace safety issues include noise, lighting and/or visibility, atmospheric conditions, the use of heavy machinery and explosives, and the potential for dangerous fumes, fires, and unplanned explosions.

Fire is one of the most lethal, and therefore most studied, issues involving tunnel safety. More frequent use of tunnels has given rise to more actual and potential tunnel fires, as well as the resulting damage and loss of life.

Tunnels generally have only two entry/exit points, which increases the difficulty of getting firefighters and equipment to the scene and the ability to evacuate people inside. In addition, the confined space of a tunnel also increases the potential for superheated flashovers; concentrates smoke, fumes, flames, and heat radiation; reduces visibility; and hinders escape and rescue.

Hazardous cargo is another significant and growing tunnel safety issue. Incidents involving the transportation of hazardous materials threaten

human life, tunnel infrastructure, and the environment, in addition to traffic flow disruption and economic losses.

The transportation of hazardous material cargo has historically received less attention than other tunnel safety issues. Thus, the regulation of hazardous cargoes in tunnels shows considerable variation both within and across local, national, and international levels, but it is a subject that tunnel risk management experts must take into consideration.

The rise of terrorism risks has been heightened in the wake of such highly publicized incidents involving transportation as the September 11, 2001, terrorist attacks in New York City and Washington, D.C.; mass transit bombings in London; and a sarin nerve gas attack in a Tokyo subway. These have raised public awareness of transportation security issues, with bridges and tunnels seen as among the more vulnerable potential targets.

Security solutions involving tunnel operations include limiting tunnel access and ensuring the proper identification of employees working in tunnels, whether construction or maintenance crews, toll operators, or others. Types of terrorist threats include arson, bombings, the use of vehicles as weapons, and the release of chemical, biological, or radiological agents.

Tunnel Hazard Mitigation

Tunnel safety and security, as well as risk management, center on the protection of structural elements, human life, and vehicles and their material cargo, as well as protecting the role of tunnels in the transportation network. Preventive measures are common to mitigate safety and security threats. Tunnel inspections help determine structural conditions and identify potential risks. Human elements such as employee information and training are also important. Many tunnel operators establish emergency response plans and first-responder training to enhance tunnel safety systems in preparation for an actual emergency.

Tunnel safety and security measures are often mandatory as well as voluntary. Many local, state, and national regulatory agencies, such as the U.S. Occupational Safety and Health Administration (OSHA), provide workplace safety regulations to govern worker safety during tunnel construction, operations, and maintenance. Worker safety guidelines or regulations can include adequate ventilation

and atmospheric monitoring procedures, and the availability of oxygen, escape routes, and safe refuges in the event escape is not possible.

Emergency ventilation, lighting, power sources, and communications systems are basic components of most tunnel safety and security systems. Tunnel communications systems are vital to both tunnel safety and security. Modern tunnel communications systems often encompass monitored surveillance equipment, such as security cameras and closed-circuit television (CCTV), as well as communications equipment such as radios and telephones. Communications systems are also designed to allow continued functionality in emergency conditions and to prevent their use by non-authorized personnel.

Fire safety systems rely on fire detection and alarm systems, designated fire lanes, and fire suppression methods such as sprinklers, fire hydrants,

and fire extinguishers. Many modern automobile and truck interiors are designed with fire-resistant materials, while tunnel equipment, such as cables, are often fire resistant or fireproof. Tunnel drainage systems to prevent or control leaks and floods include surface drainage, sump pumps and drainage pipes, and the identification of areas vulnerable to leaks.

Tunnel safety is further enhanced through the inclusion of strategically placed emergency egress points and escape routes to these points, such as walkways. These routes must be well lit and clearly identified by emergency markings and/or signage to be effective in reduced-visibility conditions. Alcoves may be provided for disabled vehicles, as well as areas wide enough for vehicles to turn around, if necessary.

Scientific and industry organizations have shown increased interest in studying tunnel safety

This photo from the U.S. Federal Emergency Management Agency shows a mock-up of a subway car used for tunnel and subway safety training at the Center for Domestic Preparedness in Anniston, Alabama, on September 5, 2012. The four-car training facility provides sample scenarios that include a tunnel collapse and the aftermath of an explosion from an improvised explosive device. Rescuers practice extricating victims and dealing with the potential release of hazardous chemicals or biological materials.

and security issues, as well as risk management. Numerous studies and recommendations, as well as meetings such as the International Symposium on Tunnel Safety and Security (ISTSS), have resulted. Although safety and security measures add cost to tunnel construction and operation, these costs are offset by reduced risk and the avoidance of the human and monetary costs associated with accidents, terrorist attacks, or other potential hazards.

U.S. tunnel security underwent extensive changes after the terrorist attacks of September 11, 2001. The Department of Homeland Security (DHS) identified tunnels as a vulnerable part of the transportation system's critical infrastructure. Security changes were designed to reduce terrorist accessibility, reduce their appeal as targets of opportunity, and reduce the potential for serious damage or loss of life if tunnels became the target of terrorism or natural disaster.

Changes included new engineering design standards, the Resilient Tunnel Project to limit water flow in breached underwater tunnels, and the Blast/Projectile Protective Measures and Design and Unified Blast Analysis Tool projects to identify structural weak points and create advanced mitigation measures. DHS also sought to identify and close illegal underground tunnels used to smuggle

drugs and illegal immigrants across the U.S./Mexico border.

University Transportation Centers

The University Transportation Centers (UTC) program is run by the U.S. Department of Transportation with the mission of establishing centers for transportation studies at American universities to advance transportation expertise and technology in the varied disciplines that comprise the field of transportation through education, research, and technology transfer activities. UTCs receive federal funding to help the government develop a critical transportation knowledge base through research covering a wide range of transportation-related issues and to educate the next generation of transportation leaders.

The education promoted by the UTC program is multidisciplinary and experiential, with a commitment to diversity in faculty, staff, and students, including involvement by students at all levels of study from undergraduate to postdoctoral and professional programs. UTCs work with regional, state, local, and tribal transportation agencies to help find solutions to challenges that directly impact their communities and affect the efficiency of the nation's transportation system.

The program defines six basic goals as part of its mission statement: (1) provide experiential learning in the context of a multidisciplinary program of

transportation education; (2) increase the number of students, faculty, and staff who are drawn to transportation programs at the undergraduate, graduate, and professional levels; (3) engage students, faculty, and staff who reflect the increasingly diverse United States; (4) develop an objective process for reviewing transportation research conducted by transportation centers; (5) support an ongoing program of peer-reviewed transportation research; and (6) make research readily available to potential users.

The UTC program was first established in 1987 in order to improve the country's competitive prospects in the international transportation industry at a time when Japan and (then West) Germany's improved tech sectors posed a threat to industries in which the United States had traditionally been dominant or a leading figure.

Originally allocated funds by the Surface Transportation and Uniform Relocation Assistance Act to establish transportation centers in each of the 10 federal regions, the UTC program was reauthorized in 1991, 1998, and 2005, each time expanding the number of UTCs to over 60 national, regional, Tier I, II, and III centers.

In 2011, efforts to eliminate congressional earmarking reduced the number of centers to just 22 for fiscal year 2012. In 2013, the Moving Ahead for Progress in the 21st Century (MAP-21) transportation bill authorized \$72.5 million for each of the fiscal years 2013 and 2014 for up to 35 competitive

grants for UTCs. These newly authorized centers are organized by research focus around one of five strategic goals: Economic Competition, Environmental Sustainability, Livable Communities, Safety, and State of Good Repair.

The grants were to be divided among five national UTCs (one for each thematic area) with an award of \$3 million each; 10 regional UTCs with an award of \$2.75 million each; and up to 20 Tier I UTCs with an award of \$1.5 million each, though actual awards made for FY 2013 were somewhat less due to federal budgetary constraints.

The new centers established by the UTC program are the following:

National UTCs

- *Economic Competitiveness*: University of Maryland, National Center for Strategic Transportation Policies, Investments, and Decisions
- *Environmental Sustainability*: University of California, Davis, National Center for Sustainable Transportation
- *Livable Communities*: Portland State University, National Institute for Transportation and Communities
- *Safety*: Carnegie Mellon University, Technologies for Safe and Efficient Transportation Center
- *State of Good Repair*: Rutgers, the State University of New Jersey, Center for Advanced Infrastructure and Transportation

Regional UTCs

- *Region 1*: Massachusetts Institute of Technology, New England University Transportation Center (Safety)
- *Region 2*: City University of New York, University Transportation Research Center (Economic Competitiveness)
- *Region 3*: Not chosen as of 2013
- *Region 4*: University of Tennessee, Southeastern Transportation Center (Safety)
- *Region 5*: University of Minnesota, Center for Roadway Safety Solutions (Safety)
- *Region 6*: University of Oklahoma, Southern Plains Regional Transportation Center (State of Good Repair)

- *Region 7*: Iowa State University, Midwest Transportation Center (State of Good Repair)
- *Region 8*: North Dakota State University, Mountain-Plains Consortium (State of Good Repair)
- *Region 9*: University of California, Berkeley, University of California Center on Economic Competitiveness in Transportation (Economic Competitiveness)
- *Region 10*: Not chosen as of 2013

Tier 1 UTCs

- *Economic Competitiveness*: University at Buffalo, State University of New York; Transportation Informatics University Transportation Center; University of Arkansas, Maritime Transportation Research and Education Center; University of Illinois, Urbana-Champaign, National University Rail Center; University of Southern California, Metropolitan Transportation University Transportation Center; University of Texas, Austin, Data-Supported Transportation Operations and Planning Center
- *Environmental Sustainability*: Maine Maritime Academy, Marine Engine Testing and Emission Laboratory; University of Alaska, Fairbanks, Center for Environmentally Sustainable Transportation in Cold Climates; University of Central Florida, Electric Vehicle Transportation Center
- *Livable Communities*: Montana State University, Small Urban and Rural Livability Center; University of South Florida, National Center for Transit Research; Western Michigan University, Transportation Research Center for Livable Communities
- *Safety*: Florida State University, Center for Safe and Accessible Transportation for an Aging Population; Ohio State University, Crash-Imminent Safety University Transportation Center; University of Iowa, Safety Research Using Simulation Center; University of Michigan, Center for Advancing Transportation Leadership and Safety; University of Nevada, Reno, Institute for Safety and Operation

of Large-Area Rural-Urban Intermodal Systems; University of Texas, Pan American, University Transportation Center for Railway Safety

- State of Good Repair: Florida International University, Accelerated Bridge Construction University Transportation Center; Michigan State University, University Transportation Center for Highway Pavement Preservation; Missouri University of Science and Technology, University Transportation Center for Research on Concrete Applications for Sustainable Transportation

Unmanned Aircraft

As the use of unmanned aircraft systems (UAS) becomes a component of daily life, one must consider what issues or concerns may arise from their presence in both existing infrastructure and society. The benefits of UAS have been widely recognized by the civilian sector through military testing and application; however, military systems are primarily used for tasks not reliant upon or regulated by the Federal Aviation Administration (FAA). When UAS are introduced into the civilian sector, a new list of paradigms become apparent that could affect regulation on issues such as see-and-avoid, privacy, FAA regulation, and pilot licensure.

In 2010, the National Aeronautics and Space Administration (NASA) finalized a report on UAS's integration into the National Airspace System (NAS) and added communications, UAS vehicle

interface design, certification, and interoperability to the growing list of concerns. The impacts of these issues weigh heavily on the individual manufacturers of UAS systems, policy makers, and the pilots and operators who plan on conducting commercial activities with them.

Throughout aviation's history, there have been many changes and radical advancements in technology that have had a great effect on the efficiency of the system. In the 1950s, jet aircraft started to infiltrate the skies, allowing people to travel greater distances at greater speeds and higher altitudes. It is important to consider that this change in the system was not simple and brought about a new list of concerns, some of which had never been encountered.

This complex change in the system could be referred to as a paradigm shift, where the system had to grow and become malleable in order to support the required changes in infrastructure. The integration of UAS into the NAS and into society is no different. It is another paradigm shift for aviation, where a new level of stability will be achieved through maturation of policy, regulation, and perceived trust in future technologies.

The path to complete success has yet to be drawn, but aviation experts and policy makers are working in a synergistic effort to understand how each issue may be addressed in order to allow advancement. See-and-avoid, automation, privacy, and regulation are primary issues affecting the implementation of UAS and must be assessed to provide the framework for UAS integration.

See-and-Avoid

In the 1950s, with jet airliners making the world a smaller place, airway designers and airspace integration experts had to derive methods to keep aircraft from having collisions. The existing infrastructure of the NAS was in need of restructuring. Since that period in history, the need for restructuring has become apparent again.

The FAA is striving for a partial integration of UAS into the NAS by 2015. This effort would include smaller aircraft operating from the surface to 400 feet weighing less than 55 pounds, along with more substantial aircraft that may operate up to 65,000 feet and travel in excess of 400 miles per hour. The issue that arises is an increased amount of air traffic in a finite area, in an airspace already crowded by commercial and general aviation aircraft.

A U.S. Air Force F-16 flies alongside an MQM-107E Streaker target drone during exercises over Tyndall Air Force Base in Florida. Military drones such as the MQ-1 Predator are able to operate up to altitudes of 18,000 feet, and some unmanned aircraft systems (UAS) may operate at up to 65,000 feet at speeds of over 400 miles per hour. The potential for incursions into the airspace of other aircraft has caused the Federal Aviation Administration to work toward partially integrating UAS into the National Airspace System by 2015.

The FAA, in an effort to advance and promote cutting-edge technology, has implied that modifications to the current system through the development and implementation of NextGen technologies will provide a viable solution to infrastructure-related concerns, effectively ensuring growth and development of the overall industry.

The current NAS is comprised of a system of Very High Frequency Omni-Directional Ranges (VOR) airways along with antiquated radar systems. The term *see-and-avoid* has become a common phrase in aviation to express the concerns of aircraft incursions both on the ground and in the air. This concern becomes increasingly prevalent with the integration of more aircraft into the existing infrastructure.

The application of Automatic Dependent Surveillance-Broadcast (ADS-B) technologies has been increasing and will likely replace systems already highly utilized by manned aircraft, such as Traffic collision avoidance systems (TCAS) that will not be approved for UAS see-and-avoid applications. The FAA has proposed a ruling that would make ADS-B

technologies a required component in all aircraft operating within the National Airspace System by 2020, ensuring more efficiency in aircraft separation for safety.

Regulations for the operation of manned aircraft depend on a number of factors regulated under Part 91 of the Code of Federal Regulations: Federal Aviation Regulations. In-flight visibility and weather conditions are important in considering whether the aircraft is under positive control by an air traffic agency or whether it is flying freely through the NAS. Both private and commercial flight operations can be considered to operate in two different regimes, which are referred to as Visual Flight Rules (VFR) and Instrument Flight Rules (IFR).

Aircraft operating under VFR are less restricted because environmental conditions do not constitute a loss of visual separation from other aircraft. Pilots operating in VFR conditions are responsible for maintaining visual separation from other aircraft.

IFR are different in that the pilot may not be able to see other aircraft because of environmental conditions. For instance, if the in-flight visibility is

reduced below one mile in uncontrolled airspace, a pilot may not have a clear view of nearby traffic. In the case of an aircraft operating in IFR conditions, air traffic control (ATC) would provide separation services through the use of radar systems.

For UAS, pilots control the aircraft from a ground control station (GCS), which is a ground-based flight deck. These systems may be as simple as a standard controller, such as a game-style joystick, or as complex as an integrated unit in a mobile command center. UAS may be controlled by a pilot or autonomously by a computer.

The type of system used to control a UAS from the ground is dependent on the type of aircraft, which may dictate the type of flights that may be conducted. For instance, smaller systems operating in the general vicinity of the user within line-of-sight (LOS) would typically be restricted to VFR daytime conditions because of aircraft and pilot limitations. Other systems, such as the MQ-1 Predator military drone, are able to operate beyond-line-of-sight (BLOS) up to altitudes of 18,000 feet, because the pilot receives telemetry data downloaded from the aircraft even though the UAS is out of sight. In this case, see-and-avoid becomes a primary concern for other aircraft operating within the same airspace.

With further integration of unmanned aircraft into the system, see-and-avoid protocols will be tested to their maximum limits, requiring research and evaluation to maintain the overall integrity of the NAS.

Automation

Automation refers to what level of control the pilot has over an aircraft. Sheridan's scale of degrees of automation defines that level of control by number, with 1 being the lowest and 10 being the highest. The measure is calculated by the presence or omission of human-in-the-loop (HITL) interaction. As the human progressively evolves out of the system, the level of automation becomes higher.

Levels of automation are important determinants for the complexity of the system and affect how policies and regulations are drawn. For instance, an aircraft classified as a level 1 by Sheridan's scale would require no computer interaction with the pilot, whereas an autonomy level of 10 would completely remove the human operator from the system. Each aircraft and pilot would require a different set of

operational guidelines and regulations in order to assure the safety of the flight crew, other aircraft operating in or around the craft in the NAS, and the general public.

The operation of UAS at a distance unobservable by the operator is referred to as beyond-line-of-sight (BLOS). This is accomplished through a satellite uplink that communicates between the aircraft and the ground control station (GCS). In this case, it may be assumed that the aircraft has a high level of autonomy where the operational aspects of the aircraft would be heavily reliant on the use of a computer.

For BLOS applications, the complexity of the system increases, causing concerns about such an occurrence as a loss in communication between the aircraft and the GCS. Manufacturers have worked to mitigate this issue by providing aircraft with a secondary flight plan in the case of lost communication with the GCS. For instance, the aircraft may "loiter" in a holding pattern to re-establish a connection or return to a predesignated point along its flight plan.

Privacy

To a society that relies on interpretation of the Constitution, Fourth Amendment protections of privacy are of the utmost concern. Many opponents of UAS imply that aircraft will be used for aerial surveillance that may infringe on an individual's rights as a U.S. citizen. This particular area of concern has become an issue in the operation of manned aircraft, too.

Lawmakers in many states have worked to pass legislation that would create significant boundaries for UAS operators. For instance, in April 2013, Idaho Governor Butch Otter signed into law the first bill in the nation protecting individuals from unfettered surveillance by UAS. Virginia also enacted a bill that would impose a two-year moratorium on law-enforcement drone use, except in emergencies. Other states, including Tennessee, are requiring law enforcement to obtain a warrant in order to use UAS.

Legislative outcomes carry a significant level of complexity. In many cases, the determination of whether the aircraft is categorized as UAS depends on its intent for use. Powered model aircraft have been in existence since the beginning of the 20th century and have had mild rules and regulations for operation.

UAS, on the other hand, with the capability of carrying payloads for surveillance, mapping, and other purposes, have been included in a different category of operation. For instance, a model aircraft may be flown recreationally with sensor equipment representative of UAS; however, if being used privately for the sole purpose of recreation, it would not be considered a UAS. The guidelines and protocols for operation can be somewhat ambiguous in nature because of the uncertainty of where legislative and government powers will take regulation in the near future.

Regulation

The FAA is the primary source for policy and regulation management for the operation of both manned and unmanned aircraft. Federal Aviation Regulations provide a framework for the operation of aircraft, regulating the certification of pilots, aircraft, and operational rules, along with a gamut of other regulations required for aircraft to operate safely.

The FAA consistently evaluates regulations and changes them periodically to represent any technologies or situations that may require the allowance of a new system or technique with regard to aviation applications. In the case of UAS, regulations require a new system with a list of similarities to manned aircraft.

In order to implement regulatory changes for UAS, the FAA must go through an outlined list of procedures and produce an amendment or new section to the existing Federal Aviation Regulations, referred to as a Special Federal Aviation Regulation.

Special Federal Aviation Regulation 107 was designed to enable small UAS to operate safely in limited portions of the NAS with a primary temporal focus of accomplishing this in the shortest rule-making time frame.

Small aircraft would be those operating in day-time VFR conditions, weighing less than 55 pounds and being flown directly by a pilot. Looking forward in legislation, this will provide the testing ground to implement rules for larger aircraft. The majority of manufacturers are developing aircraft that fit into this category and will operate below 400 feet, providing the foundation for finding operational issues and concerns that will directly translate into larger UAS regulations.

As the operation of the UAS industry matures and more civilian aircraft are developed and tested, the proper regulation will be finely tuned and evolve to provide the greatest level of safety and efficiency to the stakeholders responsible for the operation of UAS.

Unsignalized Intersections

According to the generally accepted traffic safety definition, an unsignalized intersection is simply an intersection without a traffic light, not only full stop lights (with red, green, and yellow signals), but also blinking yellow and red lights. This definition does not generally include traffic signs.

While unsignalized intersections are present in both urban and rural areas, they are more likely in rural or suburban areas. The most common type of unsignalized intersection is made up of a major road meeting with a minor road; the minor road may have a stop or yield sign, but this is not always the case. In terms of public safety, intersections,

especially unsignalized intersections, are of major concern. All types of intersections have dramatically higher accident rates than the rest of the highway system. Furthermore, unsignalized intersections pose the same risks as signalized intersections with a higher risk of fatalities.

Dangers

While they may seem quite ubiquitous to the average driver, intersections actually make up a very small part of the total American highway system. Despite this fact, accidents are dramatically more likely to occur at intersections than at other locations along roadways.

According to a study produced by the National Cooperative Highway Research Program in 2003, more than 50 percent of all crashes in urban areas occur at intersections, and more than 30 percent of accidents in rural areas occur at intersections. Furthermore, the chance of collision not only increases at unsignalized intersections but those collisions also become more dangerous. Nearly 35 percent of crashes at unsignalized intersections involve injuries and 9 percent of intersection accidents involve fatalities. In comparison, as few as 6.5 percent of fatalities occur at signalized intersections.

It may not be surprising that unsignalized intersections are far more common in rural areas than in urban areas. Also to be expected, as population and development increases, traffic at unsignalized intersections sees a corresponding increase. If this increase in traffic at the unsignalized intersection hits a critical point, and that occurrence comes to the attention of transportation officials, a stop light may be installed. Thus, while there are currently many more unsignalized intersections in the United States than signalized intersections, signals are becoming more common.

Improvements

Traffic safety officials have two basic methods through which to reduce the risk of collision. Either the situation can be improved for safe drivers or the behavior of risky drivers can be addressed. The former is far easier to address, but there have been efforts to engage the latter, as well. In order to understand efforts to reduce the risk of collision at unsignalized intersections, one must understand all the objectives improving these intersections,

then seek to understand the strategies utilized in improving those intersections.

The reasons to improve unsignalized intersections are many, and many of these reasons may not seem obvious to laypeople. This article does not provide a complete list of reasons to improve an intersection, but it does provide some of the most common and important reasons to improve intersections.

First and foremost, traffic engineers seek to reduce the frequency and severity of incidents by changing the geometric design of the intersection (for example, changes to improve driver sight distance). Traffic engineers may also seek to not only improve the availability of gaps in traffic but also to assist drivers in judging gap sizes between cars at the intersection.

Efforts may be made to improve driver awareness of an upcoming intersection as viewed from the road prior to the approach. Efforts can also be made to improve driver compliance with traffic laws at the intersection through such traffic control devices as traffic cameras. Traffic engineers may also seek to reduce operating speeds on specific intersection approaches; this can be accomplished by either lowering the legal speed limit or by making alterations to the driving environment that coerce drivers to reduce the speed of their vehicles. Finally, efforts may be made to guide motorists more effectively through complex intersections.

There are a great variety of strategies aimed at improving the safety of unsignalized intersections; this entry discusses only a few. These strategies can be divided into three classifications: proven, tried, and experimental.

Proven strategies are those that have been used in one or more locations. Additionally, strategies are proven through scientific evaluations performed by traffic analysts. After evaluation, the strategy can then be used with a good degree of confidence. Examples of proven strategies include installing left-turn lanes, providing right-turn lanes at intersections, realigning intersection approaches to reduce or eliminate intersection skew, and improving visibility for drivers by improving lighting.

Strategies that have been classified as "tried" have been implemented at actual intersections but have not been subject to scientific evaluations. Thus, these strategies may be generally accepted as improving the safety of the intersection, but they lack empirical proof. Tried strategies include

implementing driveway turn restrictions, creating longer left-hand turn lanes, providing bypass lanes on shoulders at T-intersections, restricting or eliminating the turning maneuvers available to drivers, and providing channels through median openings.

Experimental strategies are those that have been suggested and seriously considered for implementation but have yet to be tested in an experimental setting. An example of an experimental strategy is providing an automated real-time system to inform drivers of available gaps for making turning and crossing maneuvers.

Issues With Signalizing

Efforts to install signals at currently unsignalized intersections are not without controversy. There are financial costs associated with installing and maintaining signalized intersections; this could be an issue for proponents of regional and local austerity.

It should also be noted that installing signals is not a universal solution for improving the safety of unsignalized intersections; signals must be installed strategically and with purpose. If improperly installed, signals may disrupt the flow of traffic. Such disruptions can lead to delays and even dramatically increase the risk of rear-end collisions.

Upstream Signalized Crossovers

An upstream signalized crossover (USC) is a type of intersection designed as an unconventional way to handle left turns at intersections in order to improve performance. It was first proposed by Vener Tabernero in 2004, as his master's of applied science thesis in civil engineering at the University of British Columbia (UBC). Tabernero went on to become a civil engineer and has continued to publish on the topic of USCs as does his thesis adviser at UBC, Tarek Sayed.

Left turns are a significant factor in traffic flow, gridlock, and safety issues at conventional intersections, because a left turn takes the vehicle across the path of traffic perpendicular to the street onto which the vehicle is turning, whereas right turns require, at the most, joining the flow of traffic without crossing it. Further, vehicles in opposite-headed lanes turning left may come into conflict when each one turns, whereas the same pair turning right would not approach each other.

Left turns also impose a limit on the intersection's capacity and performance. Quite often at conventional intersections with traffic signals, the left-turning vehicles are the controlling element of the intersection's operation, with their presence and volume impacting the sequence and type of the traffic signal phases.

The various proposed solutions to the left-turn issue have been either measures to modify existing intersections, such as optimized signal timing or turn lanes, or designing unconventional intersections. Tabernero's thesis work introduced the USC as such a solution.

The USC is a four-legged intersection in which left-turn opposing conflicts are avoided by the left and through traffic of each approach being crossed to the left side of the road. Traffic upstream of the intersection crisscrosses, requiring four secondary signalized intersections at those upstream points, hence the name of the intersection.

Right-turn traffic remains on the right side of the road, but left-turn and through traffic crosses the median to the left side of the road, arriving upstream of the intersection. This is done in all four directions, creating the criss-cross effect and allowing left turns to be made without coming into conflict with one another.

In simulations, the USC cuts delay time and the number of crossing conflicts in half, and is able to accommodate 15 percent more traffic than a conventional intersection before failing (that is, becoming congested). As predicted, the USC is less sensitive to the volume of traffic in the left-turn lane, whereas in a conventional intersection, increased volume in left-turn lanes brings about congestion and increases delays at a much faster rate than overall volume increases.

USC intersections shift traffic to the side so that left turns are functionally similar to right turns at conventional intersections, insofar as they do not result in opposing vehicle conflicts. The redirection requires the signaling indicated in the name, and with proper coordination of the signals, the intersection can be negotiated with significantly fewer delays. The secondary intersections handle left-turn and through traffic crossing over from one direction, as well as departing traffic in the other direction, which consists of through vehicles and left-turners from the cross street. Right-turn traffic simply turns right, via a right-turn bypass, and is then merged back into traffic upstream of the secondary intersection.

The primary intersection can operate on as few as two signal phases because the secondary intersections mean there is no need for a “green left arrow” phase in which left turns are protected. The secondary intersections also operate on a two-phase cycle because they do not permit turns, and so only need to regulate approaching and departing traffic. An optimized USC coordinates the two sets of signals so that a continuous green band carries from the secondary intersection on one side of the primary intersection to the secondary intersection

An unsignalized intersection in Kharkiv City in the Ukraine in 2011. A 2003 study found that almost 35 percent of crashes at unsignalized intersections lead to injuries, while 9 percent involve fatalities. In comparison, only about 6.5 percent of fatalities occur at signalized intersections.

on the other side, with the green bands for the cross street offset to minimize the primary intersection's cycle length.

The major problem USC presents is the potential confusion of drivers at both the primary and secondary intersections, and the chance of the path through the secondary intersection inducing feelings of drivers being on the wrong side of the road. This danger seems heightened for drivers new to the USC, which might make it inappropriate for use in intersections trafficked by a large number of nonlocal drivers, such as in tourist areas or near airports or car rental agencies.

Driver confusion could occur not only when approaching the unfamiliar-looking intersection or when entering the secondary intersection, but when making a left turn, when muscle memory and habit may cause the driver to instinctively begin to turn left around the central median. This could possibly be mitigated by extending the central median, and certainly clear signage would be necessary.

Another disadvantage of the USC is that although each intersection involves fewer signal phases, the fact that there are two intersections instead of one means there are more stops, which introduces the possibility that the frequency of rear-end collisions would be increased. This is a trade-off experienced by most signaled intersections, where the traffic flow control introduced by the traffic signal reduces collisions overall but increases rear-end collisions.

It is likely that the increase in rear-end collisions as a result of having two stops is not as severe as the increase between a signaled and an unsignaled intersection, but the actual increase is unknown. Driver confusion can lead to hesitation, which can increase the frequency of rear-end collisions when hesitating drivers slow down unexpectedly.

At the secondary intersections, there may be an increased risk of crossing collisions. The angle at which cars exit the secondary intersection creates a longer path to clear the cross section than at a conventional intersection, and as a general traffic-flow rule, longer crossing distances increase the odds of the final car to cross violating a red light, which is a major factor in crossing collisions.

Urban Mass Transit Act of 1964

The Urban Mass Transit Act of 1964, signed into law by President Lyndon Johnson and based on the transportation policies of his predecessor John F. Kennedy, created the Urban Mass Transportation Administration (UMTA), which has since become the Federal Transit Administration (FTA). The act provided matching funds for cities or states to fund public or private rail projects.

The UMTA and later FTA grew beyond the scope of the original act, with funding reauthorized by later transportation bills, and provided financial and technical support for projects ranging from bus routes to light and commuter rail, subway systems, monorails, personal rapid transit systems, passenger ferries, streetcars, and people movers.

While the original bill authorized only \$375 million in funding, for instance, \$12 billion was authorized by the Urban Mass Transportation Act of 1970, and the National Mass Transportation Assistance Act permitted those funds to be used for operating costs as well as construction costs, since the issue preventing the development of many local transit systems was the impact they would have on state and local taxes. Today most of the FTA's annual budget is spent on subsidies to state and local governments.

The legislation was enacted because of the importance the government placed on ensuring the quality of mass transit and access to it in America's cities. Both Kennedy and Johnson were deeply invested in improving the living conditions of the American people, which meant addressing social and economic inequities, whether in the form of Johnson's War on Poverty or in guiding transportation development through federal policy and funding.

The three pieces of legislation together defined important aspects of federal transit policy. For instance, while the 50:50 matching funds for public transit systems was criticized by opponents at the time (and since, when reauthorization bills come up) for increasing the size and spending of the federal government unreasonably, they are noticeably less than the 80:20 matching funds provided for highway construction. This may represent in part an area of uncertainty, or maybe compromise, in policy thinking on transportation: while highways, forming the nation's interstate roadway, are a matter of clear federal interest, it is less obvious that a local subway system is a federal responsibility.

Further, because funds were initially and more substantially made available for rail projects, that dictated the choices local and state agencies made. At a time when transportation research was toying with numerous projects from moving walkways to personal rapid transit systems, rail systems ended up the most practical to adopt, from a funding perspective, regardless of their relative merits. Bus services declined, and considerably less funding was available for pedestrian, bicycle, car share, or carpool projects.

Nevertheless, the legislation was considered a good sign for the rejuvenation of America's cities, which had begun with 1961's Housing Act (which included a transportation research component in its funding targets) and continued with Johnson's Great Society programs. The era's concern for the holistic health of American cities in the face of gentrification and the onset of suburban sprawl is visible even in the children's television show *Sesame Street*, which first aired in 1969 and takes place in a diverse urban neighborhood that is noticeably pedestrian-oriented and self-sufficient.

It is common today to conflate mass transit and public transit, and the 1960s and 1970s transportation bills may be partly responsible for this, as most mass transit is now at least publicly subsidized. Public agencies were able to take over private transit companies with matching funds, though in some cases throughout the country, the mass transit system is operated by a private company that contracts with the public agency responsible for it. Mass transit had largely been pioneered by private companies that obtained the right to use public rights-of-way from local governments. The modern New York City subway,

for instance, includes rail lines originally built for the private elevated train, and the private elevated train and streetcar networks serving all five boroughs exceeded the public subway system in coverage. On the other hand, relocating the transit system to primarily underground created an overall public good—freeing up vast above-ground real estate that would otherwise be occupied by transit lines—in a way that government is uniquely suited and uniquely motivated to do.

Conclusion

While opponents expanding 21st-century publicly funded mass transportation projects sometimes construct arguments for the superiority of private mass transit systems and blame the expansion of public transit for private transit's virtual death, there is another way of looking at it. Public funding for mass transit came at a time when the automobile was finally becoming the default mode of transportation for Americans—a time when driver's licenses were being issued to the first generation to take driving for granted, right on the cusp of the spread of suburban sprawl that depended on most of its residents being two-car households. Rather than killing private transit, legislation like the Urban Mass Transit Act may have saved mass transit at a time when the popularity of the automobile was threatening to bleed it dry.

Urban Mass Transportation Assistance Act of 1970

Before 1970, federal transportation law helped subsidize highway growth in the suburbs, but during the 1970s dozens of new mass transit systems were constructed in predominantly urban areas. Many people who utilized this mode of transport did so in order to get to and from work, with many riders commuting from the suburbs to the central business district. For such a commute, in 1970, a single-ride transit fare from Queens to Manhattan in New York City cost 30 cents. The impact of the Urban Mass Transit Act of 1970 is examined in terms of the accommodation of people with disabilities, protecting the environment, the role of government, and long-standing financing.

Public Law 91-453 was a landmark in federal financing for mass transit because it provided the first long-term commitment of federal funds. Its enabling legislation was titled the Urban Mass Transportation Assistance Act of 1970, which was approved by Congress in October of 1970.

Previously, federal funds were short term; therefore, it was difficult to plan and implement mass transit projects over several years because of the uncertainty of future financing. Because monies came out of general revenues, not special taxes, it ensured long-term financing.

In section 9 of the law, Congress authorized \$10 billion of funds to be distributed over a 12-year period with \$3.1 billion available beginning in fiscal year 1971. Recipients had to match every two federal dollars with one dollar, and no more than 12.5 percent of the total budget could go to any single state. In addition, this legislation included grants to city planning agencies to incorporate comprehensive planning principles at all levels of government and administration.

Transit costs included initial construction, continual operation, periodic maintenance, and everyday management. The law funded rights-of-way, station sites, and relocation payments for displaced private property owners. Furthermore, monies could be used for the extension of existing transit systems, modernization, new buses, and retrofitting the existing transit fleet for access by the elderly or people with disabilities.

Since millions of Americans experienced immobility problems while using these systems, the federal government responded to this issue in a new manner. Legislation was inserted into the act to remove obstacles for the elderly and people with disabilities.

Mario Biaggi was a freshman U.S. congressman from the Bronx, New York, who made a name for himself when he successfully modified the bill. The Biaggi Amendment, which was embedded in section 6, asserted the equal rights of disabled persons and mandated that transit authorities make “special efforts” to accommodate handicapped persons and the elderly.

Some historians claim that the push for equal accessibility was in part due to the large number of wounded veterans returning from combat during the Vietnam War. To end the segregation of people with disabilities and the elderly from able-bodied people through the use of customized vans with door-to-door service, the existing mass transit fleet needed to be retrofitted. Accommodations included new ramps and lifts on buses, lowered bell cords, specialized seats, and improved handrails and elevators at stations. All in all, the act approved 3.5 percent of the total funds to finance retrofitting and it enabled the governor of each state to distribute funds.

At this time, the government’s role in mass transit was part of President Richard Nixon’s new federalist approach of decision making, which shifted authority away from Washington, D.C., to state and local officials. The Nixon administration named John Volpe, who was the former governor of Massachusetts and a champion of mass transit, as the secretary of transportation.

In addition, this law included provisions that required public entities receiving federal funds to enter into agreements approved by the Department of Labor to ensure that the transit authority negotiated with labor unions in order to receive funds. Previous transit programs were often opposed by labor unions because they did not protect workers. Besides supporting laborers who worked on these billion-dollar projects, this legislation also provided for the protection of the environment.

The impact that mass transit had on the environment was significant. Under section 5, the legislation dealt specifically with provisions to safeguard the environment. For example, it mandated the creation of environmental impact statements on all projects as well as the disclosure of these published reports

to allow for citizen participation at public meetings. Moreover, it required the secretary of transportation to determine if there was an alternative plan based upon negative environmental impacts.

The act was friendly to the environment because mass transit is a more fuel-efficient and cost-effective way to travel compared to driving an automobile. These provisions should not come as a big surprise because six months before the legislation's approval, Americans celebrated the first Earth Day, which engaged 20 million citizens, some of whom persuaded politicians to pass eco-friendly laws. As a result, numerous regulations to improve environmental quality were passed during the 1970s.

Overall, the important contributions of the Urban Mass Transportation Act of 1970 were diverse and consisted of reduced pollution of the environment, increased handicapped accessibility, a longer-term commitment for federal funding, less time lost by commuters as automobile traffic jams eased, and better access to jobs for people without cars.

One quantitative study showed that transit ridership increased in the cities that obtained the most federal aid, although transit usage decreased in the communities receiving the least amount of assistance. Ever since 1970, America has witnessed the creation of dozens of new rail transit systems; however, bus service ridership continued to decrease. In the end, mass transit helped lessen the country's reliance on foreign nations in order to obtain oil for vehicular transportation.

Urban Sprawl Versus Compact Development

The terms *urban sprawl* and *compact development* refer to opposite ways of using space to develop built environments. Urban sprawl refers to the way that cities expand even into rural areas, creating low-density communities taking up vast amounts of land. This also means that there is a relatively large amount of space between structures. Many see low-density development of land as wasteful, socially harmful, and, in the long run, more expensive.

The term *suburban sprawl* is sometimes used interchangeably with urban sprawl because it has often been suburbs that arose as a result of the spreading out. Urban sprawl is fueled by an automobile culture that enables people to drive long distances to get to their work spaces. This urban sprawl, fueled by the car, leads to congestion of the very roadways that brought people to less crowded spaces.

Compact development, on the other hand, conserves the use of land with a higher density of inhabitants, living in a variety of kinds of high-quality housing. Public transportation, an important partner of compact development, de-emphasizes the need for automobiles, thereby reducing the need for as much parking and reducing congestion of streets and roads.

The term *smart growth* has many of the same connotations as compact development. "New urbanism" is another movement that emphasizes, among other factors, compact development, neighborhoods independent of the automobile, and neighborhoods built with the pedestrian in mind. Urban sprawl is driven by a number of factors. The growing population of cities is one cause. An increase in demand for housing stock leads families and individuals to the market. Often land outside the city is cheaper and developers begin building subdivisions and individual homes not connected to subdivisions. As the

An area of new housing developments encroaching on a farm in Dallas County, Iowa, near the city of Des Moines in 2000. The loss of farmland like this through development can have ripple effects, such as increased dependency on corporate agriculture.

financial condition of families improves, they often want a home with more space and a bigger yard. They are driven outside the city by their desires.

There has also been a “back to nature” movement that causes some people to want to live closer to trees and wildlife. Some have experienced the negatives of the city and flee. Rising crime rates, poor urban school systems, and a decline in the quality of the urban housing stock are among the push factors that drive individuals from the city.

Impacts

The impacts of sprawl are numerous. These include a significant loss of land as property is developed in a non-dense fashion. Most buildings sit in an island of space surrounded by property that may have once been forest land, wildlife habitat, open space, or agriculturally productive fields. As sprawl has multiplied, the impact of the loss of undeveloped land has become significant.

The environment is negatively impacted through the loss of the land, whether it is loss of habitat or

loss of tree cover. Before suburban office parks, housing tracts and shopping malls, abundant farmland provided jobs for farmers and abundant harvests. Without these farms, the total population becomes more dependent upon corporate farms or imported food.

Urban sprawl can lead to drastic traffic congestion as roads into developments serve ever-greater numbers of commuters. This sprawl is also very expensive for local governments. As scattered developments are built, infrastructure must be extended. In a compact city, however, new housing is usually developed using the infrastructure components already in place or nearby, where they are simply extended short distances.

In locations impacted by sprawl, the infrastructure may need miles of expensive expansion. Local governments must also expand the availability of police, fire, and emergency medical protection. These local entities must also provide adequate school, library, and governmental service structures. Thus, urban sprawl may result in a great debt burden for local governments.

Urban sprawl can also lead to racial and economic segregation. As more affluent people, often white, move to the suburbs, they leave behind in city inner cores people with less economic opportunity, who are predominantly minorities.

Efforts to reduce urban sprawl and move to compact development have been multifaceted. One effort has emphasized redevelopment of inner cities. The basic infrastructure exists already and new housing and business development there prevents the need for additional urban sprawl. The effort can be summed up by the term *managed growth*. Uncontrolled growth leads naturally to urban sprawl and the rapid expansion of the use of land in a low-density manner.

Managed growth seeks to limit the unrestrained expansion of urban areas. It does not seek to end growth but to encourage compact development. Zoning regulations to protect agricultural and open land have been used. Eminent domain has been implemented with limited success. Financial incentives and disincentives have been used to encourage compact growth. A variety of legislative acts have also been enacted, with mixed results.

In New Orleans, after Hurricane Katrina, some parts of the city were dotted by landscapes with widely scattered surviving homes. Early in the

recovery phase, planners suggested making some of the most devastated areas green spaces while resources were freed to restore city services and utilities in less damaged areas of the city. In essence, planners were suggesting that the footprint of New Orleans be reduced and made more compact.

The loss of property tax revenue had already been significant because of the loss of homes and relocation of residents, and it was thought that the loss of tax revenue from any remaining homes that were habitable would be more than made up by the reduced services that would have to be provided. However, the opposition of homeowners, owners of the newly empty lots, and the politicians that represented them was so strong that the plan was abandoned.

Urban Trail Systems

Urban trail systems are connected open spaces located within an urban area and designed for the use of nonmotorized modes of transportation such as walking or cycling. The interest of urban planners in these systems has increased in the past few decades due to increased awareness of their benefits. The systems can enhance the livability of urban communities by improving accessibility to natural

environments, promoting healthful exercise, and facilitating human interaction, leading to important benefits in terms of public health. They also fulfill an important role in the sustainability of the urban environment.

The definition of "open space" in urban trail parlance is broad and can encompass different types of land cover and use, depending on the geographic, environmental, and social context of each city. Most urban trail systems include parks, gardens, reserves, lakes or rivers, and other spaces where vegetation is a predominant element. Riversides or sea fronts, canal towpaths, corridors along disused railway lines, and regenerated industrial areas may also be included in the system.

The main characteristics of these systems are the large number of component spaces and their connectivity, allowing uninterrupted access by nonmotorized modes, such as walking, cycling, or skating. Trail systems thus form a linear route linking different parts of a city or metropolitan area.

The concept is distinct from that of greenway because it presupposes access along the whole of the route, while greenways may include open space for the purpose of conservation and human access is partly restricted. Trail systems may also be connected with other car-free areas of the city, such as historical neighborhoods, shopping streets, shopping malls, or sport facilities. In some cases, public transit, such as electric buses or light railways, may also be allowed to use parts of the system.

Urban trail systems are a feature of many cities in developed countries. Cities in Europe have long developed trails along rivers and abandoned transportation infrastructure. In London towpaths along disused canals provide an extensive network used by walkers and cyclists. Trails may also be implemented in the space left by obsolete structures such as the Berlin Wall.

Many North American cities also have trail systems. For example, the system in Portland, Oregon, comprises a trail along the Willamette River and other streams and a network of parks and other open spaces, while in Toronto, Ontario (Canada), the lake waterfront is at the core of the project.

Most Japanese cities have also developed extensive trails along rivers. Throughout the world, urban trail systems are developing quickly following the popularity of programs promoting nonmotorized mobility, such as public rental bicycles.

One of the arguments for the implementation of this infrastructure is that it enhances urban livability. Trails can be used as corridors for walking and cycling as a means to access the workplace and urban facilities or to link nearby communities. The system can therefore facilitate human interaction and contribute to community cohesion.

People's sense of community may also increase because of the availability of places for social encounter and gathering, a role that local streets once filled but no longer fulfill effectively because of the noise, distraction, and dominance of motorized traffic.

Urban trails also increase accessibility to places with historical and cultural significance and provide spaces for recreation, cultural activities, and sport events, improving the experience of the city for both residents and visitors. The enjoyment of green and other natural areas also promotes environmental education and the feeling of closeness of humans and the natural world.

The benefits of trail systems in terms of public health are also important, because they provide opportunities for physical exercise. The benefits of walking, jogging, and cycling are widely recognized and include enhanced strength and flexibility and protection from cancer and heart diseases. These benefits are increasingly important given the current trends of aging populations and increasing obesity in most developed nations.

Living near and having the possibility of easily accessing open space and clean air also have benefits in terms of people's general physical health. Surveys indicate that outdoor recreation plays an important role in the mental health, well-being, and life satisfaction of urban citizens, allowing for relaxation and contemplation and thus providing relief from stress.

Urban trail systems offer important benefits as an alternative to daily commuting in cars, buses, and rail systems, which, research has found, is one of the most stressful activities in urban living. The trails may also provide an escape from the work environment during lunchtime breaks and from the home environment for residents in small and crowded apartments.

While urban trail systems are created for human activity, they also fulfill an important environmental and ecological role. The implementation of the systems is often done in conjunction with the revitalization of areas suffering from environmental

The Charles River Esplanade is a walking and biking path running alongside the Charles River in Boston, Massachusetts. Similar urban riverside trails can be found in London, England, and Portland, Oregon, among other cities.

degradation, such as rivers, lakes, and waterfronts, involving improvements in water quality, air quality, and a general clean up of natural areas. The inclusion of parks and natural reserves in the system, and the emphasis on their connectivity, also contributes to the conservation of wildlife and plants by helping preserve habitats and corridors for the natural movement of animals.

In addition, the presence of open space within the urban environment reduces the risk of flooding, while urban forests and other green areas have positive effects in the regulation of urban climate and air quality. The creation of facilities for the use of nonmotorized modes also contributes to a transportation modal shift, reducing traffic levels and the associated local environmental impacts, such as air pollution and noise, and regional and global effects such as the excess release of carbon dioxide (CO₂).

Urban Transportation Modeling System

The aggregate travel model, better known as the Urban Transportation Modeling System (UTMS) or the conventional four-step model (FSM), has been the dominant transportation model in the United States since the 1950s. One of the reasons it is called an aggregate model is because it uses aggregate socioeconomic (and land use) data from geographic areas, known as a traffic analysis zones (TAZs), rather than from individual household units

Development History

The aggregate travel model was first implemented on mainframe computers in the 1950s, serving as a tool for transportation planning analysis, such as identifying the most congested corridors, selecting the best freeway alternatives, and forecasting future traffic volumes and speeds. The highway orientation of the early aggregate travel model occurred naturally due to the massive wave of interstate freeway construction after the U.S. Congress enacted the Federal-Aid Highway Act of 1956. The initial model development of trip generation, distribution, and diversion led to the first comprehensive application of the FSM system

in the Chicago Area Transportation Study and Detroit Metropolitan Area Traffic Study around that time.

The 1960s brought federal legislation requiring "continuous, comprehensive, and cooperative" urban transportation planning, fully institutionalizing the FSM. Further legislation in the 1970s and the 1980s brought environmental concerns to planning and modeling, as well as the need for multimodal planning. After the enactment of the Clean Air Act Amendments of 1990, many states and metropolitan planning organizations (MPOs) have the added responsibility of demonstrating that metropolitan transportation plans conform to their State Implementation Plans, often through the reduction of mobile source emissions.

The Americans with Disabilities Act (1990), Intermodal Surface Transportation Efficiency Act (1991), Transportation Equity Act for the 21st Century (1998), and Safe, Accountable, Flexible, Efficient Transportation Equity Act: A Legacy for Users (2005) further mandated many changes in transportation modeling processes. New federal mandates, plus the completion of the interstate highway system, change in female labor participation, decentralized workplaces, urban sprawl, technological advancements, and other factors have created increasing demands on aggregate travel models, such as modeling nonmotorized transportation, truck movement, and smart growth, and integrating land uses and transportation.

The existing trip-based aggregate travel model is apparently not appropriate to meet these increasing demands. Recognizing this, the federal Travel Model Improvement Program (TMIP) was established in 1991. Much of the subsequent period has been directed at improving the state of the practice relative to the conventional FSM model while conducting new research and developing new methodologies such as disaggregate simulation of households, activity-based and tour-based modeling, integrated land use/transportation modeling, and many others.

Aggregate Travel Modeling Processes

Before transportation modeling starts, it is necessary to prepare a local land use forecast, also called small area forecasting. During this process, socioeconomic forecasts are made for the region as a whole. Such forecasts provide control totals for local land use analysis. Typically, the region is

first divided into TAZs (i.e., small areas). By trend, regression, or other type of technique, the population, employment, and other socioeconomic data are determined for each TAZ. The outputs from land use forecasting become the inputs for transportation modeling. The four steps of transportation modeling are trip generation, trip distribution, mode split, and trip assignment.

Trip generation is the first step in the traditional aggregate modeling process. The trip generation model estimates the number of person-trip ends (production and attraction) for each TAZ. These trip ends are calculated on a household, person, or employee basis and then aggregated to TAZ level.

The trip generation model consists of three steps: First, use the trip production model to estimate production trip ends by purpose by TAZ. Typical socioeconomic data elements for this model include income, automobile availability, household size, and number of workers. The important data sources are the census and household activity data. The trip production model typically uses a cross-classification model. Second, use the trip attraction model to estimate attraction trip ends by purpose by TAZ. For trip attractions, the most important data input is employment, which is broken down into basic employment, retail employment, and service employment. The important data sources are workplace and household surveys. The trip attraction model can use either a regression model or a cross-classification model. Third, balance trip productions and trip attractions to get final production and attraction trip end tables by purpose by TAZ. Since trip productions are believed to be more reliable, trip attractions are normally balanced to match trip productions for the entire modeling area, especially for home-based work trips.

Trip distribution is a way to determine where trips are coming from and going to. By matching productions with attractions, trip distribution will convert production and attraction trip ends tables from the trip generation step into trip table matrices by purpose. The most commonly used trip distribution models are the gravity model and growth factor model (also known as the Fratar model).

The gravity model takes the following equation form:

$$\text{Trips}_{ij} = \text{Productions}_i * (\text{Attractions}_j * \text{FF}_{ij} * K_{ij}) / (\sum \text{Attractions}_j * \text{FF}_{ij} * K_{ij})$$

Where:

FF_{ij} = the friction factor for TAZ_i and TAZ_j , which is inversely proportional to the travel impedance between these two TAZs; and

K_{ij} = the K-factor for TAZ_i and TAZ_j , which accounts for socioeconomic linkages not accounted for by the friction factor.

The growth factor model, or the Fratar model, is also an important trip distribution model. Many local cities use the growth factor model because they do not have the detailed friction factor and K-factor information, but they know the future growth rates and existing trip tables (T_{ij0}) in order to forecast future trip tables (T_{ij}).

There are three types of growth factor models. The first type is the uniform growth-factor model: the general growth rate g is known for each zonal pair, $T_{ij} = gT_{ij0}$. The second type is the singly constrained growth-factor model: the origin or destination specific growth factors g_i or g_j are available for each zonal pair, $T_{ij} = g_iT_{ij0}$ or $T_{ij} = g_jT_{ij0}$. The third type is the doubly constrained growth-factor model: two sets of independently determined growth factors g_i and g_j are available for each zonal pair, $T_{ij} = g_i g_j T_{ij0}$.

Mode split (also called mode choice) computes the proportion of trips between each zonal pair that uses a particular transportation mode. Mode split is determined by the relative cost/time for making the trip by each mode and the person/trip/land use characteristics, such as automobile availability, household income, household size, congestion, cost (parking, tolls, fares, out-of-pocket costs), and other factors. Some small cities do not use the mode split model because their trips are predominantly automobile trips, and the cost to develop a mode split model is rather high.

The mode split model has several techniques: analogy, elasticities, direct estimation of transit share, and the disaggregate mode split (DMS) model. Of all techniques, the DMS model is the most sophisticated and widely used; it is based on the discrete choice modeling concept developed by Nobel laureate Daniel McFadden in the 1970s and 1980s.

In the DMS model, the probability of selecting a mode is determined from utility equations, which use the concept of utility. A mode utility is

a combination of the mode's cost, travel time, and other factors that reflect the difficulty of using the mode. The higher the cost and time associated with the mode, the lower the mode's utility (i.e., the higher the mode's disutility), and the lower the probability that mode will be selected.

The most commonly used multinomial logit equation of DMS takes the following form:

$$P_i = e^{U_i} / \sum_{j=1}^n e^{U_j}$$

Where:

P_i = probability of mode i ;

U_i = utility of mode i ;

n = number of modes; and

e = natural log.

Trip assignment (also called route assignment) is the process of allocating a given set of trip interchanges to a specific highway or transit network. Highway assignment involves several algorithms. The most common are all-or-nothing assignment and equilibrium assignment.

All-or-nothing assignment assumes that the minimum impedance (travel time or generalized cost) route (path) for each origin and destination (O&D) pair is found. All flows (trip interchanges) between these O&D pairs are loaded on these routes. A given route receives all or nothing of a given O&D pair's flow, without any consideration of the capacity available on the route.

To perform all-or-nothing assignment, it is necessary to have a trip table assigned and to link information (free flow speed, time, and others) so that the uncongested impedance between the different O&D pairs can be computed. The following steps are performed: finding the shortest route between the TAZs; assigning all trips to links comprising the shortest route; continuing until trips between all TAZ pairs have been assigned.

Equilibrium assignment uses the concept of capacity restraint. Often Wardrop's principle of user equilibrium is applied when each driver (or group) chooses the shortest (travel time) path, subject to every other driver doing the same.

The concept of capacity restraint uses link flows (volumes), link capacities, and link speed to predict link impedance (travel time). The Bureau of Public Roads formula, used as a default in most model packages, shows this relationship:

$$T = T_0 [1 + 0.15(v/c)^4]$$

Where:

T = congested link travel time;

T_0 = original link (free flow) travel time;

v = assigned traffic volume; and

c = the link capacity.

This technique searches for a user equilibrium solution in which link flows and impedance are simultaneously solved. Under equilibrium conditions, traffic is assigned in congested networks so that no individual trip maker can reduce path impedance by switching routes. This assumes that trip makers know the traffic conditions on all routes.

In addition to highway assignment, transit assignment is also an important task for many agencies' transportation modeling processes, especially for large agencies. However, transit assignment is different and more complex than highway assignment because the network of transit services is different from that of vehicles. Links in this network include bus or rail service running between two stops or stations. Many of the public transit services share road links with private cars. These differences result in an assignment to a more complex network.

Unlike highway assignment, transit assignment involves the movement of passengers, not vehicles. Travel time includes both in-vehicle time and out-of-vehicle time, such as waiting at stops and walking to and from stops. Passengers also may transfer between two routes, and even drive part of the way to board a public transit service.

In a highway network, monetary cost is directly associated with fuel consumption, tolls, and parking. In transit services, the various fare structures determine the monetary cost associated with a trip. There is also transfer cost and parking if an auto is used to get to the transit station.

Model Estimation, Calibration, Validation, and Application

Model estimation includes statistical estimation procedures used to find the values of the model parameters (especially coefficients) that maximize the likelihood of fitting observed travel data, such as a household travel survey or onboard transit survey. Its focus is on correctly specifying the form of the model and determining the statistical significance of the variables.

Model calibration is used to adjust parameter values until predicted travel matches observed travel demand levels in the region. For example, calibration of the mode-specific constants in a mode choice model ensures that the estimated shares match the observed shares by mode (and often by mode of access).

To test the ability of the model to predict future behavior, model validation requires comparing the model predictions with information other than that used in estimating the model. This step is typically an iterative process linked to model calibration. It involves checking the model results against observed data and adjusting parameters until model results fall within an acceptable range of error.

The application of the model to future year conditions and policy options requires checking the reasonableness of projections, so there is a link between application and validation. The sensitivity of the models in response to system or policy changes is often the main issue in model application.

Urban Transportation Planning Process

Typically, the urban transportation planning process (UTPP) has seven steps: (1) inventory, (2) land use forecasting, (3) trip generation, (4) trip distribution, (5) modal choice, (6) network assignment, and (7) evaluation. The travel forecasting process constitutes elements 3 through 6 of the UTPP and is generally referred to as the "four-step" or "four-stage" modeling process.

Before World War II, transportation planning did not include any transport modeling/forecasting

elements. Thereafter, rapid suburbanization of U.S. cities and huge increases in federal government infrastructure spending created the need for more precise regional modeling of future travel patterns. Much of this early modeling work was developed in the Chicago Area Transportation Study (CATS), and these approaches have since been refined and improved upon considerably and incorporated into what is now a formal process—the UTPP.

Inventory

The inventory process is frequently the most time consuming and expensive component of the UTPP. It consists of the development of a database for evaluating existing travel demand and the performance of the existing transportation system. It is also the basis upon which future travel demand and transportation system requirements are estimated.

Essentially, the inventory process involves acquiring information about existing land uses, their types and distribution. It also involves surveying the population to obtain information about socioeconomic characteristics and people's travel habits, including the number of trips they take, where trips originate and terminate, and the extent to which people use various transportation facilities. Finally, an inventory of the existing transportation system is undertaken so that the capacity of the system and the characteristics of the level of service can be established.

Normally, transportation studies use some sort of areal unit system (e.g., census tract, traffic analysis zone [TAZ]) for compiling data. The exact configuration of this system is decided on at this stage and can significantly affect later analysis. During the inventory, it is also common to develop a set of networks in travel modeling software to represent the major roads and all transit lines.

Land Use Forecasting

The core objective of this element of the process is to forecast the configuration of the future urban system that any new transportation system is set to serve. This involves estimating the intensities and spatial distribution of future population, employment, and economic and social/leisure activity and how they are likely to influence future types and spatial distribution of land use.

Generally, these future trends are extrapolated using relevant existing national data (usually from

the census or other relevant sources) and land use and survey data gathered from the inventory stage. In some studies, land use models are used to forecast future intensity and distribution of land use activity over the planning horizon period (normally about 20 years). Data from the land use forecasting process is used as input for the travel estimation and forecasting process (steps 3–6).

Trip Generation

Trip generation is the first step of the four-step modeling process. It is concerned with predicting future levels of person or vehicular travel, normally for zonal units (e.g., TAZs) or a combination of such units by trip purpose and time of day. It involves estimating the total number of trips generated and attracted by each zonal unit as a function of socioeconomic, locational, and land use characteristics, which can be represented by variables that change with each zonal unit and with the time period under consideration.

Once the factors influencing travel demand have been identified for the base year, they are projected for a future year to provide estimates of travel demand. During trip generation, separate estimates are generated of trip activity at the home (e.g., home to work) and non-home end of a trip (e.g., work to recreation to shopping). The former are described as trip productions and the latter as trip attractions.

Two sets of factors are most important for influencing trip generation rates. The first is land use factors. Different land use categories (e.g., residential, commercial, retail) are associated with different trip generation rates. Similarly, land use intensity produces varying trip generation characteristics.

The second is household characteristics. These include family size, whereby higher mean values are associated with more daily trips; automobile ownership, whereby mean cars per household is associated with higher daily trip rates; type of dwelling unit; and occupational and income characteristics (higher-income households often have a greater ability to pay for movement). Beyond these, factors such as population demographics and the quality of the transport infrastructure, among other things, affect trip generation rates.

There are three general ways to forecast trip generation rates: (1) growth-factor modeling; (2) cross-classification, known as category analysis in Europe;

and (3) multiple linear regression. Growth factor modeling is rarely used in modern studies. Cross-classification aims to classify zonal household-level data into standardized subgroups (e.g., household size by automobile ownership) represented by average trip generation rates. Together with future estimates of number of households in subgroups, average trip generation rates are used to forecast trip productions and trip attractions.

Multiple linear regression is used where two or more factors are thought to affect overall trips being generated; it measures the separate influence of each factor in association with other factors in trip generation. The aim is to use base-year traffic, land use, and socioeconomic data to produce a regression equation representing the relative influence of each factor (independent variable) on the zonal trip rate (dependent variable) using the technique of least-squares fitting. This equation is then solved using future estimates of the independent variables (e.g., number of households, automobile ownership) to derive information about the number of trips generated by each zonal unit (the dependent variable) for the forecast period.

Trip Distribution

Trip distribution is conventionally the second step of the four-step modeling process, although it can be the third, depending on whether modal split is undertaken after trip generation. The objective is to distribute the forecast future total number of trips originating in each zone among all other possible destination zones. The process creates a matrix that relates origin and destination travel flows for the forecast year. For simplification, all trips are assumed to be separate, even though in reality significant trip chaining occurs. In addition, trip distribution is generally completed separately by trip purpose (e.g., home-based work, home-based other, non-home-based).

There are two sets of methods by which trips can be distributed: growth factors methods and synthetic methods. The growth factor approach was initially developed where the only information available was origin and destination total trip ends and a travel matrix of existing trip making. There are four main types of growth factor model: Uniform, Average, Fratar, and Detroit.

In all cases, the approach operates on the premise that future interzonal trip movements can be

predicted by a measure of anticipated future trip growth. The main difference between the models lies in the complexity with which growth factors are applied specifically in terms of interaction assumptions between origin and destination zones in the system. In existing practice, growth factor models are only used for short-term planning horizons.

For synthetic methods, the gravity model is widely used, but the opportunities model is also used. The gravity model states that travel (interaction) between two zones is directly proportional to the relative attraction of each zone (e.g., total population, employment) and inversely proportional to some representation of the separation between zones (e.g., distance, time). Synthetic models differ from growth factor models because they estimate future interzonal trips in the system without directly using the observed trip pattern. Modern-day models are more sophisticated than the simple gravity model and take a more realistic account of the effect of separation on interaction using a deterrence function, among other improvements.

For the opportunities methods, two approaches are generally used: the intervening opportunities model and the competing opportunities model. Both methods introduce probability theory as the theoretical basis for trip distribution. In addition, both models are conceptualized around two basic assumptions about human behavior. First, people minimize total travel time from their point of origin subject to every destination point having a stated probability of acceptance if considered. Second, the probability of a destination being accepted (if considered) is a constant, independent of the order in which destinations are considered. On this basis, the probability of trips terminating at each destination zone is estimated. Aside from the foregoing methods, entropy maximization, multiple linear regression, and linear programming methods can also be used to estimate future trip distribution.

Modal Choice

Modal choice (also known as modal split) is normally the third step of the four-step process but can sometimes be the second step. If the process occurs as the second step (i.e., prior to trip distribution) it is known as trip end modal choice; if it occurs as the third step it is referred to as trip interchange modal choice. The core objective of modal choice

modeling is to determine the assignment of person-trips to the various available modes of travel.

In the early days, this process was only concerned with splitting trips between automobiles and public transport modes, and this was a major weakness of the models; today, the majority of modal choice modeling involves the allocation of trips to all modes including walking and cycling, and indeed takes account of multimodal trips.

Numerous procedures exist for modal choice modeling, but all use the assumption that the proportion of trips carried via each mode (e.g., car, bus, cycling) is a function of the attractiveness of each mode relative to competing modes. The attractiveness of individual modes is based on a set of factors including the characteristics of the journey being made (length, purpose, time period of the journey) and the transportation system being used (travel time, monetary cost, comfort) as well as the characteristics of the individual making the journey (car ownership, income, socioeconomic status).

The exact methodological approach used for modal split varies depending on whether the process is completed as the second or third step. Trip end models allocate total person-trips to the various modes before trip distribution occurs. Thus, the extent to which they take account of the transport system characteristics is extremely limited. Most trip end models rely either on regression analysis or analytical models similar to the gravity model of trip distribution for deriving modal split (i.e., entropy maximization approaches) and are heavily reliant on individual characteristics of the user as the main determinant of modal choice.

On the other hand, trip interchange models are post-distribution models (i.e., they use as input the trip interchanges produced at the trip distribution step) and thus are more realistic in that they take account of the characteristics of the transport system. For this reason, trip interchange modeling is now widely used. Many existing city-regional models use a disaggregate modeling approach including multimodal split models (e.g., the N-way structure and hierarchical structure models) and discrete choice models, which are grounded in microeconomic theory.

Network/Route Assignment

The final step of the four-step process is network/route assignment. It is concerned with the

assignment of a given set of interzonal trip movements, by mode, to individual links on the rail, bus, and road networks. The basic assumption behind the operation of network assignment is that routes are chosen rationally by individuals to minimize travel time between origin and destination. More sophisticated models take account of other factors affecting route choice, including monetary cost and congestion, among others.

It is assumed that travel time on the route ultimately being used will be less than or equal to the travel time on other routes not being used for any given interzonal trip. The corollary here is that it is also assumed (somewhat unrealistically) that individuals are fully aware of all alternative routes that they might travel along when deciding on their choice of route. For input data, the network assignment process requires the proposed or existing transportation system as well as a matrix of future interzonal trip movements by mode, which is derived from the trip distribution and modal choice stages.

Standard procedures for assignment of future trips include all-or-nothing assignments, proportional assignments, and capacity-restrained assignments. Typically, all approaches use some variant of a minimum-path algorithm that assigns vehicles onto individual routes based on the minimum time path between origin and destination zones. All-or-nothing assignments involve loading all vehicles between a given origin and destination onto a single minimum-time path and assume zero congestion effects. Proportional assignment involves a percentage of vehicles being assigned at the outset, and then the minimum-time paths are computed after that portion of the assignment as the basis for the next percentage to be assigned. However, most modern urban transport authorities tend to use capacity-restrained assignment, in which vehicles are assigned to the shortest journey time routes for each origin–destination zonal pair.

Once a route has reached its carrying capacity, a new set of minimum time paths is derived using a set of adjusted travel times for accommodating the remaining trip movements. Thus, as vehicles on individual links slow down due to congestion, the model assigns some vehicles to other faster pathways until new assignments fail to provide travel time reductions in the system. Time of day must be represented during the assignment phase, and

normally the process is run for at least the peak and off-peak periods.

Evaluation

The final element of the UTPP has one basic objective: to decide whether or not a specific plan is worth implementing. This involves determining a range of consequences of plan implementation for users and nonusers of the transportation system and, in particular, for the environment, among other considerations. It also involves identifying at what point in time the plan will actually be worthwhile, specifically in terms of when net benefits can be realized (e.g., after 5, 10, or 15 years).

Perhaps the key difficulty with plan evaluation is that a weighting system must be devised to assign weights to each of the foreseeable consequences; this raises immediate problems with respect to how objective weights can be identified for consequences such as environmental effects that cannot be measured directly. Traditionally, monetary cost-benefit analysis has been the most widely used evaluation procedure. However, it has come under criticism for assuming that all costs and benefits can be reduced to monetary equivalents, a process that is wrought with difficulty.

Moreover, it tends to be overly concerned with user costs and benefits rather than incorporating corresponding information for nonusers. Beyond this approach, other evaluation methods such as least cost, least harm, maximum benefit, multicriteria analysis, and cost-effectiveness analysis can also be used for the process of plan evaluation.

Urban Walkways

In transportation literature, the term *walkway* is often synonymous with sidewalk. It can also refer to built paths more separated from roadways than sidewalks usually are. There is sometimes a buffer of space, often with plantings of trees or shrubs, that gives more isolation from roadways than do sidewalks. However, walkways and sidewalks are thought of together in terms of transportation policy and planning.

The Transportation Department of the U.S. government defines "urban" to be primarily towns and cities with more than 5,000 in population. The term *urban walkway* then would refer to sidewalks and other pedestrian-designated pathways in an urban area.

Sidewalks are usually built within the road or street rights-of-way. In some cities, there have been special types of walkways, built separately from sidewalks. In parts of London, an elevated walkway system was developed to help pedestrians avoid some of the congested ground-level foot and vehicle traffic. This system of walkways did not prove especially successful in part because of a lack of connectivity. These elevated walkways were often not populated with pedestrians and became somewhat scary to potential pedestrians because of their isolation. It had been hoped that an elevated walkway would lead to an additional level of commerce, but this never materialized.

Hong Kong has been successful in developing some elevated walkways separated from the dense traffic of the city. Some of these pedestrian walkways give pedestrians an avenue to avoid busy intersections. Some cities have developed underground walkways. There have also been efforts to

develop moving walkways in some urban areas to promote walking. These are often found in airports, and there may be a growing future for them on the streets of cities.

There is a growing interest in making urban areas more walkable. This refers to making it safe, convenient, efficient, and pleasant to walk to destinations within the city. The desire to promote walking is joined to the concept of making cities more bicycle friendly. Both of these are tied to the efforts to be more environmentally friendly, to reduce traffic congestion, and to promote good health through encouraging exercise.

Considerations for Planning

It is understood that for people to want to use urban walkways, there must be a presence of factors that make sure pedestrians will not be discouraged from their use. Planners and policy makers must consider a number of factors in preparation for the planning of these walkways.

The surface of the walkway must be adequate. This refers first to the width of the walkway. There is no single standard for how wide a walkway or sidewalk must be. The U.S. Americans with Disabilities Act encourages walkways to be at least six feet wide. The surface can be made of various materials, but it should promote comfort and safety. The slope of the walkway should be gradual so as not to present hills so steep that they impose barriers to use of the walkways.

Another important factor in promoting walkable cities is the presence of continuous walkways. If sidewalks are missing and people are forced into more interaction with motor traffic, then overall use of walkways will be lessened. Connectivity is important in designing pedestrian transit. If people are going to walk in the city, they must have the opportunity to easily get where they are going with walkways.

Sidewalks must be relatively free from barriers to walking. An excessive number of signposts, utility poles, and even street furniture can impede foot traffic. Though too much street furniture is to be avoided, there needs to be adequate seating so that people can rest, visit, and wait.

The density of the city needs to be such that pedestrians can accomplish many of their tasks without having to walk excessive distances. Land use should be mixed so that there are no urban

deserts in which only one type of establishment covers large blocks of territory. For instance, block after block of office buildings or warehouses without an intermixing of other forms of commerce would not promote walkability. Having shops, government offices, schools, recreational opportunities, and eating establishments scattered throughout the city promotes the use of walking and walkways.

Adequate separation of walkways from the roadways is essential. A proper buffer must be present. This buffer can be some combination of distance and barriers. Curbs are essential, and trees can give the pedestrian a sense of protection from traffic as well as provide a calming influence on the walker. Cities must also build into the transportation design ways to slow motor traffic to present less danger to the users of walkways.

The walkways should be designed in such a way that pedestrians will be able to use them in a variety of ways. For example, people should have room to stop and talk without impeding the flow of walkers. People need to be able to keep up their walking speed if they desire to do so.

Additional Factors to Consider

A lack of adequate walkways is a major barrier to a walkable city. A lack of separation of pedestrians from roadways is deadly. In cities where there may be more immigrants not familiar with traffic patterns and some unable to read English, there is an increased danger to pedestrians who do not have access to proper walkways.

Walkways, or sidewalks, should ideally be on both sides of the street. This is especially true for more heavily traveled roadways. Urban roadways should almost always have walkways on both sides.

Rural areas often do not have sidewalks along roadways. A footpath along the shoulder of the road is often all that is available. One way that walkways can be made more available is for local governments to require walkway construction to be a part of any new development. This can lead to a better level of connectivity even when the local governments may not be able to fully finance walkway projects.

Federal Support Increases

Federal funding for transportation projects has been crucial to the development of the U.S. national

A large elevated pedestrian walkway surrounds this roundabout in Shanghai, China, separating the pedestrian traffic entirely from vehicles on the roadway below. Experiments with elevated walkways in some other cities have not been successful, leading to isolated, unused facilities. However, in most cases, pedestrian activities have been found to increase when additional provisions are made for them.

highway system, and, more recently, attention has been directed to the promotion of bicycle and pedestrian transportation as well.

Each state is being required to have a coordinator responsible for looking out for the interests of pedestrians and bikers. The Intermodal Surface Transportation Efficiency Act (ISTEA), enacted in 1991, required states and metropolitan areas to develop comprehensive transportation plans, which were to include plans for bicycle and pedestrian transportation.

The Transportation Equity Act for the 21st Century (TEA-21), enacted in 1998, further defined the importance of including pedestrian and bicycle travel as transportation projects were designed. This act provided that, where feasible, as new

highway and road projects were designed, consideration should be given to providing safe routes for walkers and cyclists.

In 2005, Congress enacted the Safe, Accountable, Flexible, Efficient Transportation Equity Act: A Legacy for Users (SAFETEA-LU). This legislation accelerated the development of pedestrian urban walkways through several key provisions. One was the Safe Routes to School Programs, which provided \$612 million to be used by states and local governments, with an opportunity for private groups to receive funding as well, to help promote walking and biking to school in safe ways. Some funds were made available to provide new and improved walkways for the use of schoolchildren.

Several other provisions in SAFETEA-LU provided funding that could be used to promote pedestrian and bicycle transportation, and to ensure the safety of these modes of transportation. Walkways were improved as a result.

Congress passed the Moving Ahead for Progress in the 21st Century Act (MAP-21) in 2012. This act provided continued funding for alternative transportation initiatives, including programs that benefit pedestrians. It has been shown that pedestrian activities increase as additional provisions are made for walking.

With the increase in funding that has been made available in recent years for non-highway traffic, progressive state and local governments have been aggressive in expanding the availability of high-quality walkways and shared pathways. Shared pathways are walkways shared by pedestrians and, primarily, cyclists.

Educational funds have been provided, as well, and these have been used to educate the public about the benefits of increased pedestrian and bicycle use. The use of walkways is productive in its impact on the environment and in health benefits to those who take advantage of these urban walkways.

U.S. Department of Transportation

Throughout much of American history, transportation policies were developed piecemeal, handled by a large number of federal, state, and local agencies. Thus, the transportation sector lacked a cohesive voice in developing national transportation policies. There were 17 unsuccessful attempts to create the U.S. Department of Transportation (USDOT) before plans for its creation were finally realized.

Pressure for creating a national transportation department began to mount in the 1960s in conjunction with widespread new developments in the field of transportation. In 1961, the staff of the Senate Committee on Commerce laid out a plan in the a report, making specific recommendations for the creation of the department.

Other recommendations followed, but it was not until 1966 that Congress passed the Department of Transportation Act, which ultimately cleared the way for the creation of the USDOT and established the secretary of transportation as a cabinet-level position. The stated purpose of the new department was to establish and coordinate policies governing the operation of "an efficient and economical national transportation system." Upon signing the act into law on October 15, 1966, President Lyndon B. Johnson declared that it was "the most important transportation legislation of our lifetime."

Finding a Voice

While serving as the head of the Federal Aviation Agency in the 1960s, aviation pioneer Najeef Halaby began to understand the importance of transportation within the modern development of the United States, particularly in light of the emergence of supersonic transport. He decided that it was essential that the transportation sector be given a voice when presidents made decisions affecting transportation policy.

With the support of Charles Schultz, the director of the budget; Joseph A. Califano, Jr., a special assistant to President Johnson and various officials at the Department of Defense, Halaby approached the president with concrete plans to create the USDOT. In August 1965, Johnson selected Alan S. Boyd, a former head of the Civil Aeronautics Board, to head

a task force assigned to set up the new department. Boyd subsequently became the first secretary of transportation.

The USDOT was in operation by April 1, 1967, employing some 95,000 employees, making USDOT the fourth-largest cabinet-level department. Initially, the USDOT was responsible for all areas of transportation in the United States. It held responsibility for the Federal Aviation Administration, the Federal Highway Administration, the Federal Motor Carrier Safety Administration, the Federal Railroad Administration, the National Highway Traffic Safety Administration, the Federal Transit Administration, the Maritime Administration, the Saint Lawrence Seaway Development Corporation, the Research and Innovation Technology Administration, the Pipeline and Hazardous Materials Safety Administration, and the Surface Transportation Board.

Departmental Evolution

Over time, the USDOT evolved in response to changes in the political and social scene, as well as to those within the transportation sector. Responsibilities for mass transit were transferred to the Department of Housing and Urban Development in 1968. Under the Jimmy Carter administration (1977 to 1981), it was recommended that the Federal Highway Administration (FHWA) and the Urban Mass Transportation Administration be combined into the Surface Transportation Administration.

In 2002, the Homeland Security Act, which signaled widespread government reorganization in the wake of the terrorist attacks of September 11, 2001, transferred oversight of the U.S. Coast Guard and the Transportation Security Administration, which had been initially established as Department of Transportation Operating Administration, to the Department of Homeland Security. Within the USDOT, the Transportation Security Administration was established for the purpose of overseeing security at airports and in other forms of transportation.

About the Divisions

The Federal Aviation Administration is responsible for the regulation and oversight of all civil aviation in the United States, including passenger and cargo flights, commercial space transportation, pilot certification, civil aviation safety standards and

practices, air traffic control, the control of aircraft noise, and the environmental impacts of aviation.

The Federal Highway Administration administers the Federal Aid Highway Program, consisting of those highways funded in whole or in part with federal money, and the Federal Lands Highway Program, which is responsible for highway operation on lands owned by the federal government. In the latter role, the FHWA it works closely with land management agencies such as the National Park Service. The FHWA is also responsible for the *Manual on Uniform Traffic Control Devices*, which defines federal policy on traffic control devices, and sets the standards for traffic signs and signals and road surface markings.

The Federal Motor Carrier Safety Administration regulates the American trucking industry and is responsible for commercial truck and bus safety, among other areas.

The Federal Railroad Administration is responsible for safety regulations related to the railroads, as well as for developing national railroad policy.

The United States Maritime Administration (MA) maintains the National Defense Reserve Fleet for use in national emergencies, and promotes and operates the Merchant Marine and the U.S. Maritime Service, which trains officers for the Merchant Marine. The MA is also responsible for developing maritime trade routes, maintaining the shipyard facilities and other equipment related to national defense, and conducting maritime transportation research.

The National Highway Traffic Safety Administration (NHTSA) develops and enforces regulations related to motor vehicle safety, fuel economy, and motor vehicle theft resistance, and operates the vehicle identification number system. The NHTSA also develops crash test dummies and protocols used in vehicle safety tests. The data it produces on vehicle safety is used to develop transportation policy not only in the United States but throughout the world because of its depth of information.

The Pipeline and Hazardous Materials Safety Administration was created in 2004 and charged with the regulations for the operation of pipeline transportation in the United States, as well as transportation of hazardous materials. Its Office of Pipeline Safety maintains the National Pipeline Mapping System as part of its role in regulating the industries that use the pipeline system.

The Research and Innovative Technology Administration (RITA) was created in 2005 to coordinate the DOT's research and education programs, and it combines several older agencies, including the Transportation Safety Institute; the Joint Program Office for Intelligent Transportation Systems, which researches smart highways and other areas; and the Bureau of Transportation Statistics. Research areas in RITA include climate change, remote sensing and spatial information technologies, intelligent transportation systems, and other activities.

The Saint Lawrence Seaway Development Corporation is responsible for marine traffic in the Saint Lawrence Seaway between Lake Erie and Montreal, Canada. On the other side of the border, the Canadian Saint Lawrence Seaway Management Corporation shares the same duties.

The Surface Transportation Board inherited the railroad-related regulatory powers of its predecessor, the Interstate Commerce Commission, including regulations concerning the acquisition or construction of rail lines, the mergers of railroad companies, and the rates set by railroad companies.

The Transportation Security Agency, an agency in the Department of Homeland Security, is responsible for overseeing the security of transportation systems inside or connecting to the United States.

Secretaries of Transportation

By 1988, eight individuals had served as secretary of transportation under administrations from Lyndon B. Johnson to Ronald Reagan. In order of service, those eight secretaries included Alan S. Boyd, John A. Volpe, Claude S. Brinegar, William T. Coleman Jr., Brock Adams, Neil E. Goldschmidt, Andrew Lewis, Elizabeth Dole, and James H. Burnley, IV. In an empirical analysis of job performance conducted in 1988 for the Eno Foundation's Center for Transportation, John L. Hazard, a professor of marketing and transportation, examined overall job performance of those eight individuals, paying particular attention to budget success, legislative output, decision-making abilities, and contributions to national development. Hazard concluded that Andrew Lewis and John A. Volpe had been the most successful at heading up the USDOT and contended that Elizabeth Dole, Neil E. Goldschmidt, and Brock Adams had done the least to promote the needs of the transportation industry.

Into the 21st Century

In 1997, during the administration of Bill Clinton, the Committee on Transportation Research and Development, an interagency group, released *Transportation Science and Technology Strategy* in which the committee laid out its recommendations for bringing the American transportation sector into the 21st century. Two years later, a more comprehensive supplement to that strategy was released.

Together, the plans recommended a four-tier strategy for the role of the USDOT in developing the science and technology of American transportation. The first tier dealt with the planning and research involved in developing transportation policies in a rapidly changing world. The second tier laid out goals for forming essential partnerships that would promote the formation of new research and policies on vehicles, global air transportation, improved weather services, enhanced transportation of goods and freight, and meeting the transportation needs of the aged and disabled populations.

The third tier was concerned with enabling research into areas such as communications, designs, and national transportation strategies. The fourth tier was involved with educating and training the public and those individuals and agencies responsible for bringing transportation research and policies to fruition.

By the 21st century, the USDOT was devoting a good deal of attention to the research recommended in the two reports of the 1990s, focusing on transportation safety, mobility, human and natural environments, economic growth and trade, and national security, which has been at the forefront of the USDOT's agenda since 9/11.

During his 2013 State of the Union address, President Barack Obama proposed a "Fix It First" program designed to boost the still-shaky economy by putting Americans to work in the transportation sector.

He suggested that individuals involved in the program could be employed in the repair of 70,000 bridges that had been deemed structurally unsound, and proposed the Partnership to Rebuild America, which seeks to form partnerships with the private sector to modernize ports, improve transport of goods, storm-proof pipelines, and improve schools throughout the United States.

In Obama's 2014 budget, the USDOT was allotted \$77 billion, an increase of 6 percent over the

2012 budget. An additional \$50 billion was earmarked for revitalizing the transportation sector by investing in key areas.

The USDOT continues to work closely with state and local governments, other federal agencies, and the private sector in conducting research and in developing policies that meet the needs of a country that is increasingly affected by advancing technologies in all areas of transportation.

Value Increment Tax

The value increment tax (VIT), also variously known as the land value increment tax, land capture value tax, betterment levy, and valorization tax, is levied to capture the increase in land value that can be attributed to public investment. The tax has traditionally been proposed when the public sector is considering an infrastructure improvement, such as a subway, highway, school, park, or any other investment that increases the value of adjacent land.

Both the special assessment tax and the tax increment financing tax are variations of the value increment tax. With special assessment, the municipality levies the tax only on those who directly benefit from the improvement. Perhaps the most common form of land value increment tax in the United States is the tax increment financing district (TIFs) authorized by 48 states. Studies have shown that transportation investments have a definite impact on land value, and thus land value increment taxes are often used to finance transportation projects.

The Principle of Land Value Capture

The value of land increases when land owners fund improvements. Publicly funded investments such as improvements to infrastructure and the provision of public services can also increase the value of land. Value capture is a means for government

to recapture a higher proportion of what economists call the “unearned increment,” increases in land value that are a result of governmental actions rather than the owner’s efforts.

Similar to the site value tax in that both tax the unearned increment, the VIT differs from site value taxes in applying only to the portion of the unearned increment that is the direct result of public investment, and its purpose is to fund public investments that will raise the value of the land. Unlike property taxes, VITs do not increase with the landowner’s improvements.

Conventional property tax allows the government to capture some of the increased value of land, but the amount may be less. Moreover, because the VIT does not tax buildings and other improvements based on expenses the landowner has incurred, property owners additionally benefit from the greater value they have created at their own expense.

The VIT also has common ground with the capital gains tax on property, which levies tax on the increase in value between the acquisition price and the sale price of the land. Neither the VIT nor the capital gains tax would include in the tax assessment improvements made by the property owner only the VIT would isolate the increase in value arising from public investment as the basis of tax assessment.

The idea of the VIT is not new. Popularized in the 19th century by American political economist

Henry George, who based his arguments on earlier thinking by British political economists David Ricardo and John Stuart Mill, the central proposal was a single tax on the unimproved value of land. George believed that revenue generated by his land tax would be adequate to make all other taxes unnecessary, while at the same time avoiding the discouragement to production that was indivisible from a system based on property taxes.

Although a pure application of George's single-tax proposal is unfeasible, split rates whereby land and structures on it are taxed at different rates, with the larger portion of the combined tax rate applying to land assessments, has been adopted in some locations, including the state of Pennsylvania. As revenue from traditional sources has declined and urban population growth requiring larger investments in infrastructure has increased, value capture taxes have gained greater attention within the United States.

Special Assessments and TIFs

A special assessment is a real property tax proportionally levied on homeowners and landowners to cover the costs of public improvements that will benefit all upon whom the tax is levied. A municipality or a special district will make a decision to levy a tax for a particular improvement, such as a sidewalk or a sewer connection for a single street or a particular community. Since only those owners in the specific area will benefit from the construction, the special assessment tax is levied only against them. Typically, it is a one-time tax for a specific period of time.

All 50 states authorize special assessments, but financing mechanisms vary. For example, a municipality may issue bonds for a large infrastructure project, and the special assessment period will end when the bonds are paid off. For a more localized project, the city may choose to assess separate fees through property taxes or other assessments on a per unit (acre, square foot, etc.) basis.

Unlike special assessment, which can be used for improvements in the most affluent neighborhoods, TIFs were designed to revitalize blighted areas. First enacted in California in 1952, TIF legislation was eventually adopted by 49 states. California abolished TIFs in 2011, but they continue to be a popular means of financing infrastructure investments throughout all regions of the United States.

Under a TIF, an area is marked for revitalization and redevelopment; the annual property tax within the area is frozen at a base year, usually the year the project is authorized. It is expected that property values and taxes will increase once the improvement is made, and for a predetermined period (ranging between 15 and 50 years), the incremental property tax generated accrues to the TIF. Once the period expires, the increased revenue reverts to the municipality.

Generally, the TIF agency borrows money to fund the improvement project and pays the debt with money generated from the tax increment. Unlike other land value capture taxes that collect the tax increment before the improvement is made, TIFs collect after land value increases.

However, TIFs have been criticized for corruption and abuse, particularly in loosely defining blighted areas, and other taxing authorities such as school districts have protested their own loss of funds from increased property taxes. As a result, several states have reformed TIF legislation.

Land Value Taxes and Transportation

The 2008 Report of the National Surface Transportation Policy and Revenue Study Commission, *Transportation for Tomorrow*, advised that the country needed to invest at least \$225 billion annually from all sources for the next 50 years to upgrade the existing transport system to a state of good repair and create a more advanced surface transportation system.

The report also noted that present spending is only about 40 percent of the recommended amount. As more fuel-efficient vehicles and higher gas prices have affected fuel consumption and placed pressure on conventional sources for transportation finance, cities and states have turned to alternative means of raising revenue. VITs have been one of the strategies widely implemented.

Special assessment districts in northern Virginia will provide up to \$1 billion in funding for a \$6 billion, 23-mile (37-kilometer) extension of the region's Metrorail system being built in two phases. A Virginia law allows property owners to petition to tax themselves to pay for transportation improvements. Under this statute, 64 percent of local property owners approved a special assessment tax that will generate up to \$400 million from a tax of 22 cents per \$100 of assessed value on commercial and

industrial properties near the transit corridor. Additional funding is being drawn from federal transit grants, toll road revenues, and other sources.

Property assessments have helped fund new streetcar lines in Tampa, Florida; Seattle, Washington; San Francisco, California; and Kansas City, Missouri. The Atlanta Downtown Improvement District, a longtime champion of the city's new streetcar line, approved an allocation for transit from the district's ongoing funding of up to \$20 million over 20 years, split between construction and annual operating contributions. Funds are generated from an annual assessment of five cents per \$1,000 of assessed commercial value on 200 city blocks.

Three transportation projects in central Chicago were funded by TIFs. These projects include the Randolph/Washington station, the Dearborn subway, and various transit projects within central Chicago's "Loop." The city allocated \$42.4 million in TIF revenue to the Randolph/Washington station.

Portland, Oregon, designated the city's Gateway community as a TIF in June 2001, with a \$164 million budget to span 20 years. Both private and public developers have participated in projects, including a new transit center, a new medical building, low- and moderate-income housing, realignment of dangerous intersections, wider sidewalks, increased pedestrian lighting, and other infrastructure improvements.

With tighter purse strings at both the federal and local government levels, it seems likely that VITs will become an increasingly common tool in transit funding. Their clear connection from transit investment to the enhanced accessibility and connectivity that new transit brings, and to increased property values, makes the concept of "betterment taxes" more than a convenient political term.

Value Pricing

Value pricing represents a regulatory system that uses a variety of fees and surcharges to create variable prices for transportation that, in theory, make the cost of certain choices a truer reflection of the consequence of those choices. Because the individual cost of using a transportation network may be considerably below the marginal social cost, value pricing seeks to narrow or close this difference so that the user, rather than society, bears the costs of its shipments or movements.

Movement of vehicles and people takes a toll on the infrastructure that supports transportation, as do weather conditions and time. A lack of revenue has made maintaining the transportation infrastructure difficult for many municipalities, local governmental authorities, and state agencies. Value pricing seeks to transfer the cost of congestion, pollution, and wear and tear on the roads to the users of the transportation system. In addition to promoting equity, value pricing is seen as a way to help individuals, businesses, and organizations better understand the true cost of their transportation choices and encourage them to make wiser and more thoughtful selections as a result.

As the fate of federal tax revenues continues to be an issue of contention in the United States, value pricing is likely to grow in popularity as an option to fund transportation systems.

Background

The use of motorways, rail, air, or water for transportation has certain costs. Roads, bridges, runways, locks, ports, and other transportation infrastructure undergo wear and tear as a result of usage. Each trip or journey causes congestion and

A congestion pricing notice in London, England, in 2012. London's fee for drivers to enter the city center reduced congestion within the designated zone by more than 25 percent and led to an increase in bus ridership.

pollution. When vehicles or ships are kept in one place, land is consumed for parking, which harms the environment by removing wildlife habitats or wetlands from the ecosystem. Paved roads and runways divert rainfall, causing erosion and flooding.

While these costs are constant, government agencies and legislative bodies often defer maintenance on needed work, driving up the ultimate cost of repair or replacement. Additionally, costs of building and maintaining transportation infrastructure have traditionally been masked, as taxpayer monies subsidize roadways, airports, waterways, and other modes of transportation, making the cost of travel or transport appear less expensive than it really is.

Government subsidies offset many of the costs of transportation. The interstate highway system,

for example, was begun in 1955 as a means of better facilitating travel and transportation throughout the United States. Construction of the original network took over 35 years to complete and cost nearly \$500 billion in 2013 dollars, making it one of the largest public works projects ever undertaken. The interstate highway system was financed through a variety of sources, including tolls, bond issues, property taxes, and fuel taxes.

Nearly 40 percent of the funds that support the maintenance of the interstate highways are unrelated to users of the system. This subsidy makes it less expensive, for example, for trucks to deliver goods cross-country, but that is because of a hidden subsidy that provides an advantage over competition such as railroads, which own and maintain their own trains and railways.

Because state and local governments are responsible for maintaining and rebuilding the interstate highway system portions within their boundaries, the realization has grown that doing so takes money away from other worthwhile projects and services. The same is true for a variety of other transportation services, including ports, airports, waterways, and locks. To that end, many municipal, local, and state governments have sought ways to transfer the costs of maintenance for transportation systems to the users who benefit the most from their existence.

Shifting Funding

The United States has a tremendous need for transportation infrastructure investment. A growing population and increasing numbers of motor vehicles have increased crowding on the roads and resulted in damage to the nation's transportation infrastructure. Decreasing tax revenues have resulted in many municipal, local, and state governments deferring needed maintenance to the transportation infrastructure. This has resulted in the decline of the U.S. transportation infrastructure, which according to some rankings, has declined from sixth-best to 23rd-best in the world in little over a decade.

Congestion alone causes tremendous problems, with the average urban worker losing the equivalent of eight full days at work as a result of traffic obstructions and delays. This lost time, combined with fuel costs, adds to a loss of between approximately \$900 and \$1,600 per year for most workers. As the public and lawmakers become better aware

of the hidden costs of a declining transportation infrastructure, consensus has grown for new taxes to rebuild it. Value pricing has been a key component in this movement, both as a way to generate funds and as a means of reducing congestion.

Value pricing can take place in a variety of ways. Some municipal, local, and state governments have instituted “dynamic tolls,” whereby tolls increase when congestion is heavy or at the more popular times of the day but decrease during less busy time periods. The city of San Diego, for example, has initiated the FasTrak system, which allows drivers of single-occupancy vehicles to travel in a special freeway lane otherwise reserved for buses and carpools. The toll for traveling in the FasTrak lane varies between 50 cents and \$8, depending upon time of day and demand for the service. Annually, the FasTrak program generates over \$1 million in tolls—money that is used to fund a bus service that would otherwise not be possible.

In the United Kingdom, the City of London instituted a similar program whereby drivers of automobiles are assessed a fee to enter into the heart of the city. The assessment of this entry fee reduced congestion within the designated zone by over 25 percent and led to an increase in bus ridership. While no city in the United States has attempted this to date, several, including New York City; Portland, Oregon; and San Francisco, have examined the concept.

Shippers of freight have also begun experimenting with value pricing as a means of increasing revenues as well as regulating the flow of shipments so that they become more consistent.

The Port Authority of New York and New Jersey, for example, struggled with the issue of congestion at its seven cargo terminals in the New York City area. These cargo terminals, which constitute the largest port on the eastern seaboard and the third largest in the United States, suffer the typical difference in congestion levels between peak and nonpeak hours. In response, the Port Authority investigated whether it could use value pricing to maximize the revenues generated during the peak loading and unloading times, which were from 6:00 A.M. until 10:00 A.M.

The Port Authority discovered that some shippers were operating under significant inventory cost constraints, so that pressure for the goods to be delivered made it worthwhile to pay a surcharge for an early delivery time. For other shippers, however, increased cost in unloading goods would diminish

their profits to such a degree that selecting an off-hours delivery made sense. As a result, fees were adjusted to a flexible schedule, with unloading during prime hours more expensive than at other times.

Other Uses

As the option of value pricing to increase revenues and reduce congestion has become more broadly disseminated, its use has spread to other areas involving transportation. Airlines, cruise ships, and other transportation services aimed at leisure travelers have adopted value pricing as a way to assist them in operating with a full contingent of customers, some of whom have paid more than others.

Airlines, which were deregulated in 1978, were hit by a price war during the 1980s and saw business plummet after the recession of 1990 to 1991. American Airlines, in response to the recession, undertook an examination of its business. It found that passengers could be broadly placed into one of two categories. The first category, leisure travelers, tended to be motivated by price, with flying being prohibitive if too expensive. The second category, business travelers, were focused on the length of flight times and were less concerned with price because their plans were less discretionary than those of the other group.

American Airlines found it could increase revenues by selling tickets on its flights for varying amounts, which would change depending upon availability of seats and the number of legs in a journey. Value pricing greatly increased revenue for American Airlines, as well as its competitors, because it brought the overall price of tickets down while forcing those with less discretionary plans to pay a premium. The success of value pricing by the airlines has spread to almost all other aspects of leisure and commercial travel.

Vans

A van is a box-shaped vehicle with a platform and four-wheel-drive power train similar to a truck with an enclosed back instead of the open bed of a pickup truck. The name is derived from "caravan," a covered vehicle. In the United States, most vans are in the light-truck vehicle class, which consists of motor vehicles designed for transportation of property and that have a gross vehicle weight rating less than 8,500 pounds. Some vans, especially commercial vans, are too heavy for this classification. Most vans can be driven with a standard driver's license (provided they are not used for school transportation) and are held to a fuel economy standard based on their footprint.

The modern van was developed by American car manufacturers in the 1960s, inspired by the popularity of the Volkswagen bus. The "chicken tax," a 25 percent tariff imposed on imported light trucks (including the VW bus) in retribution for the West German ban on American chicken, slowed the sales of the Volkswagen bus in the mid-1960s and allowed American manufacturers to better compete with it on price. These compact vans met a growing demand that the bus had helped inspire.

The front of the vans was typically short, with the engine mounted in the passenger compartment between the two front seats, at least in the case of the early Ford, Chevrolet, and Dodge vans. Full-size vans followed as the engine was transferred to the front of the vehicle with a short hood, and truck-like parts and features were added. Vans made an indelible mark on American popular culture in the 1960s and 1970s, such that the children of that era grew up to become the young parent demographic to whom minivans were then marketed in

the 1980s and 1990s, before the popularity of sport utility vehicles (SUVs) threatened the minivans' market share.

Types

There are numerous types of vans. The classic large, boxy van is called a full-size van, though modern full-size vans are more aerodynamic and curvy than their predecessors. While most vans are equipped with at least one set of back seats, they may be sold with only front seats, or rear seats may be removed by the owner in order to create a cargo van. The cargo hold of a cargo van may be accessible from rear-opening doors, side doors, or both, depending on the model.

Cargo vans are frequently used by people in trades that require them to transport equipment to a short-term work site, such as exterminators and animal control, home repair and home improvement, carpet installation, home media installation, air conditioning and heating work, cable and telephone repair and installation, and therapeutic massage. Musicians frequently use vans to transport their instruments, amplifiers, and other equipment. Cargo vans are also commonly used as delivery vehicles.

In the 1970s and 1980s, conversion vans were especially popular. They were full-size vans that had been outfitted by third-party companies to become something resembling a mobile living room. They ranged from the simple—in the 1970s, the conversion process often involved little more than carpeting the interior and adding seats, decoration, and a stereo system—to the complex, as many 1980s features overlapped with those offered by camper vans and included small kitchens and full entertainment centers.

Other vans are converted for business use by traveling sales representatives, media crews, and others who modify their vans to contain a small office in the back where work could be done on the road or while on assignment away from home.

The large passenger accommodation of full-size vans, which can transport up to 15 passengers depending on the model, has led to a number of passenger transport uses in cases where using one vehicle is of greater convenience than using several but using a bus is impractical. Children's outings can be planned around a van, for instance, reducing the number of adults whose services are needed to

Three European news organizations' vans were converted to carry satellite broadcasting equipment in 2010. The 25 percent tariff on imported light trucks in the United States, known as the "chicken tax," helped lead to the development of today's types of compact vans built by American manufacturers. The tax remains in effect after 50 years.

drive a vehicle as compared to cars, which can transport only four or five passengers.

Teenagers have long used vans to travel in groups to concerts and other events, reducing the number of legal drivers needed to take them where they're going. Churches, after-school programs, and other groups often use vans to take youth groups to outings and events, and community centers and retirement homes do likewise for the elderly.

Vans are easier than many other vehicles to convert for use by the disabled and can more easily be modified to accommodate a wheelchair. They are popular for use for paratransit for that reason.

Vans are also used to shuttle passengers between the airport and hotels, and between parking lots and final destinations (such as the workplace for commuters, or stadiums for sports fans), and in demand-responsive transit services such as Dial-a-Ride.

Minivans are smaller vans designed as passenger vehicles and have less cargo space than full-size vans, and usually less power; in some ways, minivans have more in common with a car than with a truck and are popular especially with families with

young children because the automatic rear doors make it easier to get babies and toddlers in and out of the vehicle. Until recently, nearly all minivans had front-wheel drive; four-wheel drive has become more common.

At the other end of the size spectrum within the passenger van category is the camper van, often just called a camper or RV (for recreational vehicle), which is taller than most vans in order to provide sleeping accommodations. The accommodations are not as complete as in motorhomes, however. Campers rarely include a toilet, though they may have a sink. Often there is a kitchen with a gas or electric heating element and a small refrigerator.

One type of commercial van is the step van. Step vans are used as delivery vehicles, especially for carriers with large delivery fleets, such as the postal service and its private-sector analogues, courier services, and similar businesses. They are also used for local deliveries by businesses that need to make deliveries to their customers on a daily or weekly basis, including commercial bakers, and are sometimes called "bread trucks" for that reason.

Step vans are constructed to be easily stepped in and out of by a driver who needs to do so frequently in the course of delivery work. In some cases, the sliding door is left open for most of the work period for further ease. These vehicles are similar in design, and in some cases, form the basis before modification to the utility vehicles used by some fire departments, police units, and other emergency responders as mobile command units.

Vehicle Emissions Standards

Vehicle emissions standards have emerged in various contexts over the last 40 years for a variety of reasons, and while diverse in approach, each program has the long-term objective of increasing the fuel economy of vehicles in the fleet. The first such measure was the introduction of the Corporate Average Fuel Economy (CAFE) standards. Following the 1973 Organization of the Petroleum Exporting Countries (OPEC) oil crisis, the U.S. Congress passed a series of measures to lessen the country's dependence on imported oil, including the CAFE standards, which required the car industry to increase the efficiency of vehicles (cars and light-duty trucks), with requirements weighted by vehicle sales, in the United States.

Different limits were set for both passenger cars and light trucks, which contributed to some of the

challenges that the standards have faced since their introduction. Indeed, the CAFE standards have been the subject of much controversy and criticism over their lifetime.

People drive much more today than they did in the 1970s and ownership patterns have also changed, with more consumers choosing sport utility vehicles (SUVs) and light trucks over conventional passenger cars; the former, by nature, are less fuel efficient. Because of these factors, combined with automobile manufacturers' focus on improving the internal combustion engine (ICE) rather than on developing alternative fuels and vehicles, CAFE has done little to actually reduce the total fuel consumption of the U.S. road-based fleet.

CAFE Standards

The U.S. Congress initially set fuel economy standards for passenger cars at 18 miles per gallon (mpg) from model year (MY) 1979. This standard was due to run through to 2002, but in 1985, it was increased to 27.5 mpg.

The light-truck standard was set at 20.7 mpg in 1979 and this standard ran through to 2002. The standards for light trucks was increased to 22.2 mpg for MY 2007.

The Energy Independence and Security Act (EISA), which came into force in 2007, changed the way in which the CAFE standards could be set. The revised rules set standards for MY 2020 for light trucks, passenger cars, and SUVs in combination. It stated that the manufacturers' combined fleet average must be at least 35 mpg for MY 2025. Medium-duty trucks were subsequently added to CAFE regulations from 2012, with regulation of heavy-duty commercial trucks introduced in 2014.

In 2009, a landmark agreement between the President Barack Obama administration, the states, and the car industry was made to harmonize the existing efforts under "one national program" delivering fuel-economy standards, but also delivering greenhouse gas emissions (GHG) reductions at the same time. The key stakeholders in the partnership are the National Highway Traffic Safety Administration (NHTSA), a branch of the U.S. Department of Transportation (DOT), the U.S. Environmental Protection Agency (EPA), and the California Air Resources Board (CARB).

The NHTSA and EPA are responsible for setting the fleetwide fuel-economy standards and the

GHG standards, respectively; and CARB is responsible for ensuring the delivery of the standards for those states that have subscribed to the more stringent greenhouse gases standards set by California in 2002 (which accounts for around 40 percent of the national fleet), and for ensuring consistency so that the country as a whole is working to one of the two standards.

Working together, the partnership split the period 2012 through 2025 into two phases. In 2010, the parameters for the 2012-to-2016 period were set with the aim of delivering 35.5 mpg in MY 2016, and the carbon dioxide (CO₂) per-mile standards were set by EPA at 250 grams for the same time period. CARB has agreed to comply with these standards. Phase two of the program, which will cover the period from 2017 to 2025, will see the standards reduced to 163 grams of CO₂/mile in terms of tailpipe emissions and 54.5 mpg in terms of fuel economy.

It is expected that a combination of efficiency measures and the adoption of alternative vehicle technologies will be utilized in order to achieve the fuel economy and GHG tailpipe emission reductions. A midterm review using the latest available data is due no later than 2018 for the remaining period to 2025.

California's Low Emission Vehicle Program

California has a history of preemption with regard to air quality standards in the United States because its Air Resources Board was established in 1967, predating the 1970 amendments to the 1963 Clean Air Act. California can go over and above federal standards and is the only state allowed to set such parameters. It is therefore not surprising that a number of developments surrounding clean cars have subsequently come from the state.

The Low Emission Vehicle and Clean Fuels regulation was introduced by the California Air Resources Board in September 1990 and became informally known as LEV I. It was the first program to link measures addressing fuel and vehicle technologies as a system, as opposed to focusing on one aspect or the other.

This law introduced six emissions categories: Zero Emission Vehicles (ZEV), Transitional Low-Emission Vehicles (TLEV), Super-Low-Emission Vehicles (SLEV), Partial Zero-Emission Vehicles (PZEV), Ultra-Low-Emission Vehicles (ULEV),

and Super-Ultra-Low-Emission Vehicles (SULEV). LEV I was concerned with conventional air pollutants, as opposed to GHGs. Specific mandates were also made at the time for the introduction of ZEVs; it required 2 percent of all vehicles brought to market by auto manufacturers in California by 1998 to fulfill zero-emission criteria.

Following the Clean Air Act Amendments of 1990, the U.S. government also set emissions standards for light-duty vehicles, with Tier I emissions standards phased in from 1994 to 1997 and Tier II standards from 2004 to 2009. A transitional National Low Emission Vehicle (NLEV) standard program was also run between 1999 and 2003, adapting the national standards to account for California's stricter standards.

While a relatively unheard of concept before the introduction of the regulation, the ZEV mandate component of LEV I emerged as the primary, and also the most controversial, outcome of the program; it is now considered a standalone policy while the other components of LEV I have progressed separately.

LEV I covered the period between 1994 and 2003. Following its introduction, other states in the country wanted to apply California's—as opposed to federal—standards. More than 10 states and the District of Columbia now adhere to California's standards. LEV I was reviewed in 1996 and subsequently LEV II standards were introduced in 1998 to cover the period from 2004 to 2010.

CARB adopted LEV III amendments to the regulations in 2012, both making criteria pollutant standards more stringent and including GHGs for passenger vehicles in the standard. These updates will be introduced across MY 2015 through 2025.

Renewable Fuel Standard

The Renewable Fuel Standard (RFS) is a federal program managed by the EPA that was introduced by the Energy Policy Act of 2005. It was subsequently expanded by the EISA in 2007. Its primary focus is increasing the amount of renewable fuel contained in conventional fuels year-on-year, rising to 36 billion gallons by 2022. There are several categories of renewable fuel (including cellulosic biofuel, total advanced biofuel, and biomass-based diesel) included in the standards, but each of these fuels must be lower in emissions than the fossil fuel that it is replacing.

Low Carbon Fuel Standard

Distinct from the RFS are the recent developments that have taken place with regard to Low Carbon Fuel Standards (LCFS). The most common low-carbon fuels include biofuels, gases such as compressed natural gas (CNG) or liquefied petroleum gas (LPG), electricity, and hydrogen, although these are technologies that have not yet achieved mainstream market penetration.

The LCFS has gained prominence over the last five years; CARB was the first authority to establish an LCFS in 2007, which was adopted in 2009 and implemented from 2010. California's program seeks 10 percent reduction per unit of energy by 2020. Similar standards have subsequently been adopted in British Columbia and Ontario in Canada. Several other U.S. states including Maine, New York, Massachusetts, and Pennsylvania are considering proposals to adopt an LCFS following California's developments in this area.

In Europe, the Biofuel Directive mandated European Union (EU) countries to include biofuels in their fossil-based transport fuel, with the aim that by 2010 5.75 percent of all transport fuel would be replaced by biofuel substitutes. The United Kingdom (UK) also introduced a Renewable Transport Fuel Obligation Program (RTFO), requiring transport fuel suppliers to ensure that 5 percent of fuel for road-based vehicles would come from sustainable (primarily biofuel) sources by 2010.

Both programs have been largely unsuccessful as a result of two shortcomings. First, the regulations were not based in the carbon intensity of the fuels, allowing the directive to have very little impact on reducing GHGs from total fuel consumption. Second, as has been the case in the United States and elsewhere as well, the land use and food production challenges that have emerged since the introduction of the directive, the RTFO, and subsequent policies have resulted in mass opposition to the promotion of biofuel substitution.

Cars and CO₂

Standards specifically dealing with GHGs have been developed outside the U.S. context, too. Regulations (EC) NO 443/2009 (Cars and CO₂) was a bill that went into force in Europe in 2009 following the failure of the European car manufacturers to reduce tailpipe emissions through industry-led voluntary agreements. Cars and CO₂ mandates that

100 percent of new cars sold in 2015 should emit no more than 130 grams of CO₂ per kilometer, rising to 95 grams of CO₂/km by 2020.

While the bill does not specify how these targets should be achieved, giving the car companies a relative amount of freedom to use a mix of vehicle improvements and alternative fuels, it allows for an "integrated approach" whereby the bulk of emissions are reduced by fuel-efficiency improvements, with the additional amount being achieved by "complementary measures." A lack of clarity as to what is covered under the additional provisions endures while the auto industry pushes ahead with delivering against the targets set by the regulation.

Vehicle Fleet Emissions

It is becoming increasingly accepted that climate change is not only a consequence of natural temperature fluctuations but that human activities are enhancing these natural variations through the

emission of carbon dioxide (CO₂), nitrous oxide, methane, and hydrofluorocarbons (cumulatively known as the greenhouse gases) into the atmosphere.

One of the most significant contributors to greenhouse gas emissions is the transportation industry. The rapidity of growth in the passenger vehicles market experienced over the last few decades has provoked intense interest and regulatory activity. Controlling and limiting the emissions of passenger vehicles is a widely adopted approach falling under the broader international commitments toward mitigating and adapting to climate change.

With the number of cars on the world's roads exceeding 1 billion and the appetite for car travel and car ownership growing, many countries have looked to the mechanisms available to reduce the environmental impacts of the car industry. While some countries have had some measures in place for decades, whether voluntary or regulatory, other countries, particularly industrializing countries such as Brazil, Russia, India, and China (the BRIC countries) are beginning to recognize the need to take action on tailpipe emission limits. Regardless of the longevity of mechanisms encouraging reductions in passenger vehicle emissions, it is clear that the automotive industry is one of the most regulated industries.

Clean Air Act and Amendments

Per capita greenhouse gas emissions in the United States are four times the world average, according to the World Resources Institute, and the transportation sector accounts for approximately 30 percent of the nation's total emissions. The Clean Air Act (CAA), incorporated in the US Code as Title 42, Chapter 85, along with its amendments (CAAA) in 1990, establish under Title II, s.202 emission standards for new motor vehicles or new motor vehicle engines.

The CAA specifies that emission standards are to be based upon establishing classes or categories of vehicles or engines, and that these categories should be based on gross vehicle weight, horsepower, type of fuel used, or "other appropriate factors."

The rationale for using weight as a means of setting classes (or bins, as they are known) was grounded in the findings of studies that examined the effects of vehicle weight and size on accident fatality risk and concluded that reducing vehicle weight is the most significant factor in decreasing the number of fatalities. Therefore, adopting

advanced lightweight construction not only significantly reduces CO₂ emissions at the tailpipe but also contributes to road safety and accident prevention.

Corporate Average Fuel Economy Regulations

Enacted by the U.S. Congress, the Corporate Average Fuel Economy (CAFE) Regulations set fuel consumption standards for vehicles and light trucks, which applied to the overall fleet sold in a given year by a manufacturer. These emission standards for light-duty vehicles have been phased in through tier standards.

Tier 1 standards were phased in progressively between 1994 and 1997. The standards applied to all new light-duty vehicles (LDVs), including passenger cars, light-duty trucks, sport utility vehicles (SUVs), minivans, and pickup trucks. Vehicles included were identified by a gross vehicle weight rating (GVWR) of less than 8,500 pounds.

Congress left the levels of fuel economy of light-duty vehicles to be set by the Environmental Protection Agency (EPA) and National Highway Traffic Safety Administration. These targets were much less stringent than those established for passenger cars, and the industry responded by adding weight to vehicles. This experience showed that by subjecting heavier vehicles to less stringent targets, the regulations encouraged manufacturers to increase the mass of smaller vehicles to bring them outside the purview of regulatory measures.

Tier 2, which was adopted in 1999, introduced more stringent emission limits and made changes to the standards in order to address the issues of emission reduction avoidance through adding weight to vehicles. Tier 2 increased its scope to cover medium-duty passenger vehicles (MDPV) rated between 8,500 pounds and 10,000 pounds GVWR and used for personal transportation.

Those vehicles with heavier engines and identified as commercial vehicles are regulated under the heavy-duty engine emission standards. Engines in commercial vehicles above 8,500 pounds GVWR, such as cargo vans or light trucks, continue to certify to heavy-duty emission standards under 40 Code of Federal Regulations (CFR) Part 86. It is telling, not only in the early limited effectiveness of the U.S. CAFE Regulations, but also by the extension of scope to include larger vehicles under Tier 2, that capturing vehicles that traverse the boundary between passenger and commercial vehicles, either by definition

or by weight, can have a significant impact on the achievement of reduced CO₂ emissions.

The proposed rule for Tier 3 was signed by the EPA on March 29, 2013. The proposal introduces new emission standards and reflects the more stringent emission standards already established in the California emissions regulations (LEV III) standards. The structure of Tier 3 standards is similar to the Tier 2 standards in that manufacturers must meet fleet-average emission standards for their vehicles in a given model year.

Proposed Tier 3 standards include a fleet average non-methane organic gas (NMOG) and nitrous oxides (NO_x) limit that must be met by each manufacturer. The fleet average NMOG + NO_x limit is to be phased in starting from 2017 and introduces a level of 30 milligrams/mile in 2025. Importantly, the Tier 3 fleet average limit is applicable to all vehicle categories.

California Emission Standards

California emission standards have traditionally been more stringent than the EPA requirements, with other states, including Oregon, New York, Florida, Maryland, and New Mexico, choosing to adopt the California low emission vehicle (LEV) standards. Differences include that the same standards are applied regardless whether the vehicle is diesel or gasoline fueled.

Although the California LEV II program was similar in structure to the federal Tier 2 legislation, there were a number of differences regarding overall fleet emission stringency, durability, and categorization of vehicles. One difference was that the federal approach uses eight certification “bins” to allow averaging across a greater level of emission diversification in the fleet. Another important difference is that in 2010, the federal fleet average NMOG emissions, around 0.090 g/mi, based on Bin 5, was more than twice as high as the LEV II NMOG levels. This was a result of the wide scope of emissions covered by the standards.

California LEV III standards were adopted in early 2012 and will be phased in between 2015 and 2025. The LEV III standards modify the LEV II standards in several ways: (1) combining NMOG and NO_x standards into one NMOG + NO_x standard, (2) introducing a more stringent combined NMOG + NO_x fleet average requirement for 2015 to 2025 model years, (3) adding several emission

standard bins, and (4) increasing the durability requirements for emission control systems. It is of no surprise that the federal regulations have responded to the success of the California LEV standards by reproducing similar requirements under the proposed Tier 3.

European Union

In the European Union (EU), regulation of vehicle emissions was established initially as a voluntary measure. However, with slow progress being made by the industry, the European Commission adopted in 2009 Regulation (EC) 443/2009 (hereafter, the 2009 Regulation). The 2009 Regulation established mandatory CO₂ emissions reduction targets for passenger cars with an overarching target of 120 g/km for the entire average new car fleet to be reached by 2015. This target is set up to be reached gradually by manufacturers, with the longer-term target of 95 g/km as average emissions for a new car fleet from 2020.

These lead-in times, just like the phase-in times for the emission tiers in the United States, is based upon the understanding that the industry requires predictability and time in order to adapt to change. The reduction in CO₂ emission targets laid down in the 2009 Regulation is focused on a fleetwide average of manufacturers rather than a prescription for emission performance standards to be met by every passenger vehicle produced by a manufacturer independent of the segmentation. This enables heavier vehicles to have greater emission levels and these are intended to be offset by lighter, more-fuel-efficient models.

The way in which the 2009 Regulation envisages compliance with the CO₂ emission target is predominantly by means of improvement in vehicle technology, with a smaller reduction in CO₂ emissions obtained through additional measures in the form of “other technological improvements.” These factors include but are not limited to the following:

- The fitting of tire pressure monitoring systems
- The fitting of gear-shift indicators
- The promotion of low rolling resistance tires
- The reduction of emissions of specific fluorinated greenhouse gases in mobile air conditioning units fitted in motor vehicles

Manufacturers will be given a target based upon the sales-weighted average mass of their vehicles. The 2009 Regulation provides for flexibility in the way in which manufacturers choose to meet their targets; they can either meet them as an individual manufacturer on a fleetwide basis or alternatively decide to form a pool comprised of a number of manufacturers for the purpose of meeting their CO₂ emissions obligation. Where the manufacturer or pool fails to meet its specific emissions target an “excess emissions premium” will be applied on the basis of the number of new passenger cars manufactured.

The absence of measures within the 2009 Regulation placing CO₂ emission targets on heavier vehicle categories entitles manufacturers wishing to bring to market these sorts of vehicles the ability to omit these vehicles from the CO₂ emission reduction requirements. It also has the potential to encourage manufacturers to design heavier rather than lighter SUVs, the same type of perverse effect experienced in the United States following the introduction of the U.S. CAFE Regulations.

The EU blocked this possibility, however, through the adoption of a regulation setting emission performance standards for new light commercial vehicles as part of the EU’s integrated approach to reduce CO₂ emissions from light-duty vehicles.

Other Countries

Other countries with notable vehicle fleet emission reduction targets include, but are not limited to, Japan, China, Australia (only voluntary measures in place), Canada, and South Korea.

In Japan, legislation was introduced by the Ministry of the Environment to control nitrous oxide (NO_x) from vehicles under a 1992 law. The regulation was tightened in June 2001 and included new provisions relating to the control of particulate matter (PM). This 2001 law introduces emission standards for specified categories of in-use highway vehicles, including commercial goods vehicles regardless of the fuel type. The emission limits apply not only to new vehicles, but also to older vehicles already in use. To comply with the legislative duty, vehicle owners have two options. They can either replace their old vehicle if it does not meet the standard with a vehicle that does, or they can retrofit their old vehicle with approved NO_x and PM control devices. Japan is currently

A researcher at ManTech Environmental Technology in Denver, Colorado, performs an automobile emissions test on a chassis dynamometer, which cradles the car's wheels in rollers to simulate road driving during test procedures.

determining a standard for passenger car fuel economy for 2020.

Canada considers regulations to be vital in its efforts promoting clean transportation. To this end, the government of Canada has introduced greenhouse gas emissions standards for new cars and light trucks for the 2011 through 2016 model years. These standards harmonize with U.S. standards. Similar standards are forthcoming for new heavy trucks. In addition, Canada's Renewable Fuels Regulations 2010 require an average of 5 percent renewable content in gasoline and 2 percent renewable content for diesel fuel. These small steps have a positive cumulative effect on the level of vehicle emissions.

In New Zealand, the Land Transport Rule: Vehicle Exhaust Emissions 2007, which was amended in 2012, is the main measure for controlling vehicle emissions. It sets emissions standards for vehicles entering the New Zealand fleet and for those

operating on New Zealand roads. The rule requires vehicles to demonstrate that at the point of manufacture or modification they complied with, at a minimum, an approved vehicle emissions standard relevant to their class and fuel type.

While the market for passenger vehicles is accelerating rapidly with the economic growth China is experiencing, the China Ministry of Industry and Information Technology (MIIT) issued its proposed Phase III fuel consumption regulation for passenger cars, which is aimed at reducing the fuel consumption of new passenger vehicles to 167 grams of CO₂/km by 2015. Comparatively, this target appears less ambitious than other emissions reduction targets set for vehicles worldwide.

While vehicle fleet emissions are capped in a number of countries either by the setting of legislative minimum standards or through the introduction of voluntary emission reduction commitments, other strategies exist to reduce emissions. These measures include new automotive designs, fuel source alternatives (for example, the use of electric vehicles, hybrid vehicles, fuel cell technologies, and smart cars), the implementation of eco-driving techniques, car sharing or car clubs (for example, Zipcar), and vehicle and gas pricing policies (which can result in different consumer choices in relation to car purchase and to different transport mode choices). All of these strategies aim to increase efficiency and reduce the environmental effects associated with the automotive sector.

In addition, the economic downturn may encourage people to use or buy more fuel-efficient vehicles to save money, which will lower fossil-fuel energy use, reduce carbon emissions, and change the composition of the vehicle fleet.

Vehicle Miles Taxation and Fees

Vehicle miles traveled (VMT) is the total number of miles driven by all vehicles within a given time period and geographic area. VMT is an indicator of the travel levels on the roadway system by motor vehicles and can be used to gauge a vehicle's impact on the roadway. VMT-based charges have been considered as an alternative or supplement to the existing fuel tax that supports federal transportation.

Fuel Tax Versus VMT-Based Tax

More than 75 percent of current federal highway funding and a large portion of the state funds come from motor fuel taxes. Fuel taxes encourage motorists to drive less, manufacturers to incorporate fuel-saving technologies in new vehicles, and consumers to choose more fuel-efficient vehicles. Less driving was done when the fuel prices went up in 2008, for example.

There is an increase in the manufacturing of fuel-efficient vehicles in the recent past, and consumers have started looking to these vehicles as a solution to lower their driving expenses. These fuel-efficient vehicles also generate fewer environmentally damaging emissions and lessen energy dependency, which are considered important by many consumers. However, there is a concern that, with the shift to more fuel-efficient technologies and alternate fuels, the fuel tax revenue will be reduced in the coming years.

In the current tax system, vehicles using fuels other than fossil fuels (especially electric vehicles)

will not be taxed. Another concern is that the fuel tax does not directly deal with the amount of driving. Because the vehicle fleet has varying fuel efficiencies, it is possible that a fuel-efficient car will drive longer distances and actually pay less tax than a less-fuel-efficient car that is driving smaller distance. One solution to both these problems, suggested by many, is a VMT-based tax.

How Does It Work?

The VMT-based system relies on measuring the number of miles driven by each vehicle. This is expected to be achieved through the use of on-board Global Positioning System (GPS)-based systems. It could be a separate unit or a part of a preinstalled GPS unit. The data collected could be manually read during an annual inspection or registration renewal.

Other options are VMT detection using localized infrastructure, such as tolling gantries and cell phone towers, or via satellites. Those charges could be based on selective facilities (certain highways) or geographical zones. The charges could potentially vary based on the vehicle type so as to take into consideration the varying amount of pavement damage a vehicle makes (for example, passenger car versus trailer trucks). These variable charges based on location and vehicle type could also be used in conjunction with congestion management approaches, which could include variable charges based on time of day.

Another important aspect is the method of payment of fees. The payment could be processed at the gas pump at the time of fueling or through periodic billing. For the consumer, charging at the pump would mean minimum change in the way they are charged now with a fuel tax. However, it would require systems to be installed at the gas stations. Periodic billing would require more sophisticated central systems but allows for weekly or monthly charging.

The Debate

The merits of a VMT-based tax have been debated for a long time in the transportation and public policy circles. The proponents of a VMT-based tax argue that it allows for a reliable and sustainable funding option. Because the steady supply of gasoline is uncertain and there is a move away from gasoline to alternate fuels, the tax based on fuel could

begin to vary considerably and become unreliable. The political reluctance of the public to increasing fuel taxes is also a concern.

A VMT-based tax is also more equitable because it is levied based on one's amount of driving and use of the road system. While the energy dependency on other nations and emissions are related to the fuel itself, the larger share of direct costs from maintenance of roadways, congestion, and accidents are related to the miles traveled. VMT-based tax also allows for varying charges for different vehicle types depending on the potential damage to the infrastructure. Thus, the system could optimize highway use by charging higher fees during congested travel times to assist in congestion management. The increasing adoption of technologies in vehicles to allow for monitoring the VMT is considered helpful in assessing the length and time of driving.

However, the critics of a VMT-based tax point to a number of problems associated with it. Unlike a fuel tax, the VMT-based tax does not offer an incentive for drivers to buy more fuel-efficient vehicles, which might hamper the move toward more environment-friendly transportation.

There are many concerns about privacy of drivers because the VMT system depends on tracking the movement of each vehicle, which in turn is a proxy for tracking the driver. Therefore, it would be important to ensure that the data collection process, storage, and use occur in a secured manner.

This system would have significant up-front costs for equipment and monitoring systems. The phase-in process could also take many years. Social equity issues (for example, people in rural areas might have to pay more because they are more isolated, and the poor might have to pay a higher proportion of their income than the affluent) need to be resolved.

Current Status

The gasoline price, gas tax, and VMT charges would behave as a system. Therefore, careful analysis of their relationships and different scenarios is required to arrive at sound public policies. Various agencies in the United States at the local, state, and federal levels have begun assessing the efficacy of vehicle mileage fees as a replacement for the current taxes or as a supplemental funding mechanism.

One of the first pilot studies carried out in the United States is the Mileage Fee Concept and Road User Fee Pilot Program by the Oregon Department

of Transportation (ODOT). Launched in 2006, ODOT equipped vehicles with onboard data collection units that recorded mileage driven within specific zones. Customers were charged a mileage-based fee at the gas pumps after subtracting the fuel tax. The study found that the system is viable without compromising customer privacy and comfort, as well as acceptance from the customers.

The University of Iowa Road User Charge Study sponsored by the U.S. Department of Transportation has found similar potential. This study covers locations in a number of states and participants varying in age and education characteristics. Outside the United States, Germany has a VMT-based fee system for trucks. Austria, Switzerland, and the Czech Republic also have similar systems.

of the travel levels on the roadway system by motor vehicles. It is used by regional transportation and environmental agencies for planning purposes.

The Federal Highway Administration (FHWA) uses VMT and total lane miles to determine the distribution of federal funding among the states. VMT is routinely used not only to measure the amount of traffic on roads but to calculate important statistics including traffic fatalities, fuel efficiency, and air quality. VMT is influenced by factors such as population, age distribution, number of vehicles per household, and land use. VMT-based charges have been considered as an alternative to the existing gas tax that supports federal transportation funds.

Significance and Measurement

VMT has been a critical transportation indicator for many years. It gives a clear picture of a road's usage daily, weekly, monthly, or annually. Such information could then be aggregated to neighborhood, municipal, county, state, or national levels for various analyses. While VMT can be used for federal and state funding distribution, it can also indicate the changes in development and travel patterns in a geographical region. It can also show the most congested roadways and extent of sprawl.

The FHWA requires state departments of transportation (DOTs) to provide annual highway statistics including VMT estimates as part of the Highway Performance Monitoring System (HPMS), which divides roadways into 12 functional classes and traffic into four vehicle classes.

Defined by the FHWA, HPMS is "a national level highway information system that includes data on the extent, condition, performance, use, and operating characteristics of the nation's highways." State DOTs often collaborate with local governments and metropolitan planning organizations (MPOs) in collecting and reporting the traffic counts.

VMT is usually calculated from traffic counts taken on interstate, state, county, and city roadways. Traffic counters are electronic devices that can determine how many vehicles pass a specific point. Other traffic counts performed as part of the planning and design processes are also used in the state VMT calculation.

The HPMS data form the basis of the analyses that support the biennial Condition and Performance Reports to Congress. These reports provide

Vehicle Miles Traveled

Vehicle miles traveled (VMT) is the total number of miles driven by all vehicles within a given time period and geographic area. VMT is an indicator

A solar-powered automatic traffic counter in use on an Austrian road. A loop of sensors, seen here as rectangular lines in the pavement, registers passing vehicles. Traffic counts obtained from devices like this contribute to calculations of vehicle miles traveled, or the total number of miles driven by all vehicles within a given time period and geographic area.

a comprehensive, factual background to support development and evaluation of the administration's legislative, program, and budget options. They provide the rationale for requested Federal Aid Highway Program funding levels.

States usually take counts from a sample of highways and roads. The sampling sites represent a cross-section of functional class and traffic volume categories. The counters collect continuous traffic data and create a measure called average annual daily traffic (AADT). AADT is then multiplied by the distance measured to determine the total vehicle miles traveled for that section on the average day.

Multiplying this number by 365 will get the annual VMT. The localized traffic counts are aggregated to create VMT totals based on geographies, roadways, and vehicle types. Geographies could

be municipalities, counties, metropolitan regions, states, or the country.

The roadways are divided into urban and rural jurisdictions based on U.S. Census urban/rural boundaries. They are further divided into different functional classes—interstate, freeway, principal arterial, minor arterial, major collector, minor collector, and local streets. Usually, these data sets also collect information on vehicular types—passenger cars, buses, other passenger vehicles, single-unit trucks, and combination trucks.

MPOs use travel forecast models to estimate VMT in their jurisdictions. Though they are not actual counts, the model is calibrated with counts from more locations and functional classes than HPMS. This allows for a more robust estimation of VMT in the MPO region. However, the accuracy of

the estimation depends on the trip-generation and trip-distribution methods and parameters used in the network model.

Other data sources for estimating VMT include fuel sales, trip-making behavior, household size, household income, population, number of licensed drivers, and employment. These data can be obtained from the U.S. Census Bureau or from surveys.

Overall VMT Trends

In the United States, VMT is available by state, functional system, highway category, and vehicle type. The annual VMT, as well as the per capita VMT in the country, was increasing steadily over many decades until 2003, when the VMT started stabilizing and showed a decline from 2008.

VMT is a function of economic activity, transportation price, transportation supply, and sociodemographics. The stabilizing of VMT could be attributed to the stabilization in the above-mentioned factors. A more dramatic decline can be seen in the per capita VMT, which is the result of a combination of reduced growth in population and people's driving. The decline in VMT in the last five years or so could be attributed to high fuel prices and the affinity of the younger generation to live in downtown areas and closer to work places.

Factors Influencing VMT

There are many factors affecting the increase or decrease in VMT. Because VMT is the result of vehicular travel, the number of drivers and types of vehicles on the road are the most important factors in estimating whether VMT will increase or decrease. As the population increases, the number of potential drivers also increases. If these added people drive their own vehicles, VMT will obviously increase.

Because owning a vehicle is related to an individual's economic condition and affinity for or dependence on owning a vehicle, VMT increases in better economies, especially when people prefer to own vehicles. However, if the individual prefers not to drive a vehicle but to use transit, biking, or walking, the VMT might not go up.

Thus, the state of the economy, number of drivers, and number of vehicles directly influence the VMT. As mentioned, the mode of travel also matters. Even if the population increases, if the added travelers choose to use transit or carpool instead

of an individual auto, VMT can stay low. The same effect is possible if they prefer to bike or walk to their destinations.

The land development pattern has a large influence on the travel modes and VMT. In a concentrated development, people live, work, and shop close by and the need to travel by vehicle and the distance traveled will be low. One of the reasons for increased VMT is the sprawling land development pattern. Sprawl is the dispersion of land development to the suburbs and rural areas typically with low-density development. Such development is associated with new roads and longer travel distances. It also causes serious destruction of forest and agricultural land as well as waterways and wetlands. Such a development pattern also allows for more biking and walking.

However, in a "sprawl" development, people live farther from central business districts with residential, commercial, and office uses separated from each other. Such a development pattern necessitates more and longer travel by vehicles, often individual automobiles.

Both demand and supply factors play a role here. Sprawl development demands more roads. In response, developers, municipalities, and transportation agencies construct more roadways. This additional supply of roadways propels more travel.

Added road supply could also be a response to issues such as congestion. In order to relieve congestion in an area, alternate routes might be developed. An unintended consequence, again, is more travel. This is a result of phenomenon called latent demand.

Many people decide not to travel during the most congested time periods or use alternate travel modes when there is congestion in the area. However, if there is extra supply of roads, these same people could decide to travel at busier times or move back to their own vehicle from an alternative, thus increasing the demand. This increased demand will balance out the additional supply added through extra lanes or additional roads.

Telecommuting options are expected to reduce the work-related VMT. However, its impact on overall VMT could be low.

Fuel price and transportation price are key factors influencing VMT. As fuel prices increase, the tendency for people to drive alone goes down, thus reducing VMT. This trend was prominent after

2008, when gas prices went above \$4 per gallon in many parts of the United States. This might foreshadow a situation where VMT will reduce drastically only if the gas prices go significantly higher in the future.

However, it should be noted that, historically, gas price inflation is followed by a deflation and corresponding spike in VMT. Because the VMT did not go back to pre-2008 levels after the price deflation following the 2008 high, it could be assumed that there are other factors influencing the reduction in VMT.

The price of travel also matters. High toll prices, congestion charges, and parking charges have tended to reduce the VMT. This is partly by people cutting down on the inefficient trips and encouraging trip chaining, carpooling, and nonmotorized travel.

Issues With Increasing VMT

Increasing levels of VMT have direct and indirect effects on the economy, environment, and public safety. Increasing VMT might not only put more stress on infrastructure, such as roads and bridges, but could also lead to increased congestion. While more economic activity could lead to more travel, increasing VMT could be considered as an indication of better economic conditions.

On the other hand, this increased travel will lead to quicker deterioration of road pavement and bridges, leading to economic costs of repair and reconstruction. In a weak economy, such costly investments would be very difficult.

If a large part of this travel occurs on specific routes at specific times, the result is traffic congestion. It is well-documented that congestion results in economic costs, including lost productive hours, energy consumption, pollution, and poor public health. The Texas Transportation Institute's (TTI's) survey of mobility in 439 urban areas in the United States showed that in 2011, traffic congestion resulted in 2.9 billion gallons of wasted fuel and 5.5 billion hours of lost time stuck in traffic. TTI put the cost of this delay and wasted fuel at \$121 billion in 2011. Therefore, while VMT can be a measure of freedom of movement, it has negative impacts.

An increase in VMT points to other issues too. It could result in higher emission of pollutants as long as the current vehicle technologies continue. This could result in deterioration of human health

and climate change. The use of fossil fuels increases greenhouse gases and transportation is responsible for roughly one-quarter to one-third of those greenhouse gas emissions.

In addition to changes in vehicular technology, changing driving behavior to reduce VMT could reduce these negative impacts. Further, it is documented that increasing per capita VMT can result in increased traffic accidents.

Reducing VMT

As mentioned above, reduction in VMT has a number of benefits. Because increases in VMT can have negative impacts on the environment, emissions, safety, and fuel consumption, it is safe to assume that reducing VMT should reduce these impacts. However, there are different opinions about reduction in VMT. Some people argue that VMT is an indication of economic status of a region and reducing the VMT should not be the focus of public policy. They suggest that policies should aim at reducing congestion rather than VMT.

There is general consensus that a combination of congestion pricing, demand management techniques, targeted capacity addition coupled with pricing (for example, heavy occupancy toll lanes or HOT lanes), alternative modes of transportation, and compact land use policies would represent a reasonable package of policies for addressing congestion in metropolitan areas.

The most widely accepted argument for reducing VMT is its environmental impacts. Because emissions and energy consumption are directly related to the amount of driving, any reduction in VMT will also reduce emissions and energy consumption. In fact, the reduction of VMT is an official goal of U.S. government policy as it is stated in sections of the Clean Air Act, Climate Change Action Plan, Congestion Mitigation Air Quality Improvement Program, and the transportation regulations from the 1990s.

Recently, land development and its influence on driving have received close attention. The proponents of compact development argue that sprawl development causes disproportionately high increases in VMT and environmental destruction. Many of the "smart growth" principles try to bring different types of land uses (primarily residential, commercial, and office uses) together. This is expected to reduce the need for vehicular travel

and encourage biking and walking. This depends not only on closeness of activities but also on a built environment that is comfortable, safe, and reliable.

VMT Charges

There is a long-standing debate in transportation and public policy circles on the merits of charges or fees based on a person's length of driving. Such a VMT-based charge is proposed as an alternative to the fuel taxes as a source of federal transportation funding. More than 75 percent of the current federal highway trust account and a large portion of the state funds come from motor fuel taxes.

Irrespective of fuel tax or VMT charges, any reduction in VMT will result in a reduction of available federal funds. However, with the increasing trend of alternate fuels and more fuel efficient technologies, it is likely that there will be further reduction in the use of gasoline. This could result in a reduction of gas-based tax even if VMT increases.

Thus, VMT-based charges could be a more direct user fee based on actual usage of highways and local roads regardless of the vehicle type. Also, even in a reduced VMT scenario, a congestion-based VMT charge could generate sizable revenue. The VMT, gasoline price, gas tax, and VMT charges behave as a system. Therefore, careful analysis of their relationships and different scenarios is required to arrive at sound public policies.

Vehicle Ownership Models

The dependence of U.S. households on the automobile to pursue daily activity travel patterns has been the subject of increasing research study in recent years because of the far-reaching impacts of this dependence at multiple societal levels.

At the household level, automobile dependency increases the transportation expenses of the household; at a community level, automobile dependency contributes to social stratification and inequity among segments of the population; at a regional level, automobile dependency significantly impacts traffic congestion, environment, health, economic development, infrastructure, land use, and energy consumption. In addition to the overall impacts of vehicle ownership and use on regional quality of life, vehicle ownership and use also plays an important role in travel demand forecasting and transportation policy analysis.

From a travel-demand-forecasting perspective, household vehicle ownership has been found to impact almost all aspects of daily activity travel patterns, including the number of out-of-home activity episodes individuals participate in, the location of out-of-home participations, and the travel mode and time-of-day of out-of-home activity participations.

In addition, households' vehicle ownership and residential location choice are intricately linked. Thus, it is of interest to forecast the impacts of demographic changes in the population (such as aging and rising immigrant population) and vehicle acquisition/maintenance costs (for example, rising fuel prices), among other things, on vehicle ownership and use. From a transportation policy standpoint, a good understanding of the determinants of

vehicle ownership and use (such as the impact of the built environment and acquisition/maintenance costs) can inform the design of proactive land use, economic, and transportation policies to influence household vehicle ownership, which can be used to reduce traffic congestion and air quality problems.

In the past couple of decades, there has been increasing interest in not only examining household vehicle ownership and use but also investigating the composition of the household vehicle ownership by vehicle type. This is because the type of vehicle used for travel has very important implications for transportation planning and operations, as well as fuel consumption and greenhouse gas (GHG) emissions.

This is particularly of interest because of the increasing diversity in the body type of vehicles held by households, mainly attributable to a shift from small passenger cars to large non-passenger cars. In the United States, for example, light-duty trucks (including pickup trucks, minivans, and sport utility vehicles, or SUVs) accounted for just about 20 percent of the fleet 25 years ago they now account for about one-half of all vehicles.

This dramatic shift in the vehicular fleet composition and utilization has implications for roadway capacity, because larger vehicles take up more room on roadways than smaller vehicles. The resulting reduced capacity exacerbates the problem of traffic congestion caused by increasing motorized personal-vehicle use. Further, Environmental Protection Agency (EPA) statistics show that an average van, SUV, or pickup truck produces twice the amount of pollutants emitted by an average passenger car.

Developing Models

Clearly, it is important to accurately predict household vehicle ownership by type, as well as the vehicle miles traveled (VMT) by vehicle type to support critical transportation infrastructure planning and projecting mobile-source emission levels. Further, GHG emissions and fossil-fuel energy dependence are tied closely to vehicle type, leading to a much more concerted effort to develop accurate models of household vehicle holdings (by vehicle type) and use.

Three broad issues in the development of such models relate to (1) the dimensions used to characterize household vehicle type, (2) the determinants of vehicle holdings and use decisions considered in the analysis, and (3) the model structure employed.

Several dimensions can be used to characterize household vehicle type. The most commonly used dimensions of analysis in the existing literature include body type (such as sedan, coupe, pickup truck, SUV, and van), make/model, fuel type, and vehicle acquisition. However, many earlier studies have examined vehicle type using an aggregate vehicle type classification and in the context of the latest vehicle purchased by the household (or the vehicle that the household intends to purchase next), but they have not modeled the entire household vehicle fleet using a fine level of vehicle type classification.

This can be attributed to the computational difficulties in model estimation associated with focusing on the entire fleet of vehicles and/or using several dimensions to characterize vehicle type. Recent advances in econometric estimation procedures and formulations have made it feasible today to do so.

There are several determinants of household vehicle holdings and use decisions, including household and individual demographic characteristics, vehicle attributes, fuel costs, travel costs, and the built environment characteristics (land use and urban form attributes) of the residential neighborhood. Many earlier studies have focused on only a few of these potential determinants.

For instance, some studies exclusively examine the impact of household and individual demographic characteristics, such as household income, household size, number of children in the household, and employment of individuals in the household. Some other studies have identified the impact of vehicle attributes such as purchase price, operating cost, fuel efficiency, vehicle performance, and external dimensions, in addition to demographic characteristics. More recent studies also consider the impact of the driver's personality and travel perceptions on vehicle-type choice, as well as the impact of the built environment on vehicle ownership levels.

Modeling Methodology

In terms of modeling methodology, several types of discrete and discrete-continuous choice models have been used in the literature to model vehicle holdings and use. Most of these studies use standard discrete choice models (that is, multinomial logit, nested logit, or mixed logit) for vehicle ownership and/or vehicle type, and a continuous linear regression model for the vehicle use dimension (if this second dimension is included in the analysis).

These conventional discrete or discrete-continuous models analyze situations in which the decision maker can choose only one alternative from a set of mutually exclusive alternatives. However, this is not representative of the choice situation of multiple-vehicle households, where households own and use multiple types of vehicles simultaneously to satisfy various functional needs of the household.

The analysis of such choice situations requires models that recognize the multiple discreteness in the mix of vehicles owned by the household. Such models have been developed recently and applied to vehicle holdings (by type) and use. But these tend to be estimated using cross-sectional data and represent static models that do not consider the dynamics of household vehicle purchase and disposal decisions.

The application of such static models at different and closely spaced time points can lead to the unrealistic situation of a household holding very different vehicle portfolios between the two time points. However, such static models may be reasonable over longer time periods.

Another formulation that seeks to more consistently reflect the actual household vehicle holdings decision process is the dynamic vehicle transaction approach, in which households decide on disposing, adding, replacing, or maintaining the status quo of their current vehicles over time, as well as the attributes of any new vehicles entering their household vehicle fleet. The dynamic approach is particularly appealing for short-to-medium-term forecasts. However, such transaction models require commitments to collecting longitudinal data over several years. Besides, the theoretical linkage between usage and vehicle type holdings is rather tenuous in most dynamic models to date.

Conclusion

In summary, much remains to be done in developing behavioral models of household vehicle fleet composition and utilization choices—and connecting such choices to activity travel decisions and energy and emissions estimates.

There is a particular need to develop microsimulation models of household vehicle fleet and use and to integrate these with activity-based travel microsimulation models. Doing so will not only provide information on how policy makers may be able to incentivize the ownership and use of

small, fuel-efficient, and alternate-fuel vehicles but also will examine the impacts of policies on activity and travel patterns, GHG emissions, and fuel dependence.

Methodologically speaking, there is a need to use longitudinal data and develop hybrid models that combine the theoretical basis used to motivate static cross-sectional models with the more realistic time-dependent and dynamic process of vehicle holdings behavior.

Another important issue that has not been adequately addressed in the vehicle ownership and utilization literature is that there may be spatial interaction effects in household vehicle ownership and type choice that are both observed and unobserved. Vehicle choices that households make are likely to be influenced by their interactions with neighboring households and the choices that neighboring households make.

If a household observes that many of its neighbors own and drive hybrid electric vehicles, or hears good reviews about such vehicles from neighbors who already own and drive them, then the household may be motivated and influenced to also own and drive a hybrid electric vehicle. Spatial interaction effects may also arise from unobserved attitudinal preferences whereby households with similar lifestyle preferences cluster together in neighborhoods that have built-environment attributes conducive to their lifestyle choices.

Visual Pollution

The term *visual pollution* is usually applied to describe the negative effects of man-made structures on people’s perception and enjoyment of the surrounding environment. The concept is subjective, because it depends on one’s aesthetic views, but is often related to aspects such as the disruption of visibility, irregular or incoherent patterns, clutter, juxtaposition of different types of visual elements, and predominance of certain shapes and colors.

The transportation system can be an important source of visual pollution. Large transportation infrastructure can have a disruptive presence in the visual environment, especially in the case of elevated highways and railways. Some features of the design of vehicles can also be regarded as visually unpleasant by some people.

Secondary elements in the transportation infrastructure, such as signs and billboards, can also reduce the aesthetic value of the travel experience for users of the infrastructure. The recognition of the negative impacts of transportation in terms of visual pollution has led to the introduction of laws and public policies to limit or to regulate the quantity and type of elements intruding in the landscape. Despite the recognized effects of visual pollution

on human well-being, there is still relatively little research or methods for its measurement and evaluation.

Elevated highways have a considerable visual effect on people at street level. Because of their large size, they disrupt the perceptions human beings have of the surrounding environment. This is especially true in the case of major junctions, or areas with multiple elevated highways at different heights. Exposure to these effects can be particularly unpleasant in conjunction with exposures to other types of road pollution, such as air pollution and noise. In addition, measures for mitigating pollution (such as noise barriers) may also contribute to visual pollution due to their size, shape, or type of material used.

The scale of the infrastructure is a crucial factor in the aesthetic experience of people at the street level, as it contributes to the monotony of the visible landscape while they are walking. The size of the road and its position at a higher level can also be intimidating for pedestrians, especially when combined with vehicles at fast speed. The presence of transportation infrastructure also affects people’s views from their houses and offices.

Elevated railways have similar visual aspects. The size and position of the infrastructure, combined with the speed of trains and their associated noise and vibration, can be intimidating for the people at the street level and for residents and workers in buildings facing the line.

While most research on visual pollution has focused on the effects of the infrastructure, the traffic on that infrastructure may also have negative effects on the visual environment. In the case of road traffic, important elements include the shape of cars and the reflections from their metallic and curved surfaces and from windshields. These elements can be perceived as alien to the streetscape and, more generally, to the natural and built environments and can be alienating for pedestrians.

This factor may contribute to what some sociologists identify as the unequal relationship of power between car users and pedestrians. When moving at high speeds, vehicles can be intimidating for people at the street level. However, even when parked, cars also can be perceived as a visual nuisance by the pedestrian. Lights from cars can interfere with the pedestrian travel experience and increase pedestrian accident risk when walking along or crossing roads.

The elevated New York City subway system train tracks above this street in Brooklyn, New York, are an example of transportation infrastructure that can have an effect on pedestrians' experience of the surrounding area. Both the size of the railway and the noise or vibration of the trains can be intimidating for people on the sidewalks and for residents and workers in buildings facing the line. Visual and noise pollution created by such infrastructure can contribute to the isolation of some neighborhoods.

Little research has been done on the positive or negative visual effects of other vehicles, such as trains, trams, and motorcycles on human well-being. The analysis of the case of trains and trams may provide interesting results, given the relative popularity of "trainspotting" as a hobby in some countries.

Certain types of road design can also be a source of visual pollution for pedestrians. The expansion of the road infrastructure usually creates traffic islands and other "no-go" areas for pedestrians, which tend to be perceived as visually unpleasant. Traffic furniture also causes visual pollution. In the case of highways, this effect is related to the number and concentration of traffic signs, road markings, and billboards.

Together with other infrastructure, such as telephone and electricity poles, this furniture contributes to an aesthetically unpleasant clutter. Signs

and billboards also disrupt the travel experience of pedestrians, because of their size, the types of material used, and the absence of meaning to them. In the case of railways, large depots and areas with multiple service lines also create an intrusive footprint on the visual environment.

The degree of visual intrusion of transport infrastructure and traffic on pedestrians depends, however, on the context of each area, including its functional use (for example, residential, industrial, recreational, or other), the type of buildings (private houses or high-rise blocks), the presence of other positively pleasant elements, and the climate and other natural characteristics of the area.

The negative visual impact of large transportation infrastructure and traffic on that infrastructure can influence human welfare at many levels. The long-term exposure to unpleasant or intimidating

views can aggravate psychological conditions such as stress and depression. The effect is especially relevant in the cases of residents of buildings facing elevated highways and railroads. The problem may also affect residential satisfaction, because it has been reported in many studies as a factor explaining why people are not happy with the area where they live.

The visual footprint of transport infrastructure also contributes to the dividing of communities and to the isolation of some neighborhoods, with negative resulting effects on community interaction and social cohesion. The visual element is especially important because people need to cross over or under the infrastructure to access nearby communities.

Footbridges place the individuals in close contact with the transport infrastructure and traffic, amplifying the negative aesthetic effects, while underpasses tend to be perceived as ugly and dangerous environments. Visual pollution also affects the levels and quality of mobility of pedestrians and cyclists. Recent research has shown that the negative visual aspects affect the propensity of people to walk, although it is not always possible to disentangle these aspects from the overall negative sensory experience of road traffic.

Visual aspects are also relevant to the users of the transport infrastructure. Because cars move at a fast speed, the aesthetic experience of car travel is associated with the size of the visual field. The presence of elevated highways reduces this visual field and is therefore disruptive. Elevated highways can also cause disorientation for car drivers and passengers, especially around major junctions.

The reduction in visibility caused by signs and billboards also raises safety issues for drivers, as these structures compete for their attention, despite the fact that the mission of some signs is to improve safety by alerting drivers to road conditions.

Measurement

Because of its subjective character, the assessment of visual pollution is fraught with problems, which can prevent their inclusion in transportation project evaluation. The measurement of visual pollution has seen only a few developments, although authors have suggested measurements, such as the degree of intrusion of transportation infrastructure in the visual field.

The evaluation of the economic and social costs of visual pollution is also an under-researched field. A possible, though imperfect, method to estimate this value is to analyze differentials in residential prices and rents in areas with high and low levels of transport-related visual pollution. Because of the difficulties in measurement and evaluation, however, the issue may not be considered a priority in road and urban planners' decisions, especially when compared with more tangible local environmental aspects, such as air pollution and noise.

Nevertheless, aesthetic issues have slowly been included at the level of the design of new transportation infrastructure. In some countries, there are regulations regarding aesthetic elements, while professional bodies and researchers have also produced sets of recommendations to guide the visual arrangement of new transportation infrastructure.

These include, for example, the need to reduce clutter and to minimize the number of large traffic furniture. In the production of these regulations and recommendations, judgments are inevitable, especially regarding the definition of the features that are aesthetically unpleasant.

Recent developments in information technology could potentially contribute to the reduction of street clutter. For example, the use of technology such as the Global Positioning System (GPS) can contribute to the reduction of the number of traffic signs, because it allows information to be passed directly from the traffic control system to drivers.

Volatile Organic Compounds

Transportation creates emissions that can have deleterious impacts on public health. Emissions that emanate from motor vehicles or any other device that moves from one location to another are typically known as mobile sources of emissions. These consist not only of on-road vehicles such as cars and trucks but also off-road vehicles such as all-terrain vehicles (ATVs) or snowmobiles, as well as non-road vehicles such as airplanes, locomotives, and certain types of lawn and garden equipment.

One of the most common pollutants is volatile organic compounds, also known as VOCs. According to the U.S. Environmental Protection Agency (EPA), a VOC is any compound of carbon—excluding carbon monoxide, carbon dioxide, carbonic acid, metallic carbides or carbonates, and ammonium carbonate—that participates in atmospheric photochemical reactions.

In more basic terms, these are all substances that contain carbon and evaporate easily. There are numerous VOCs also emanating from non-mobile sources, or stationary sources, such as oil and gas operations, paints, and cement factories, to name just a few. Some of the more common VOCs include benzene, typically emanating from exhaust fumes from cars in attached garages; formaldehyde, typically used as a disinfectant for biological specimens; and chlorofluorocarbons (CFCs), which were widely used as refrigerants, propellants in aerosol applications, and solvents before being strictly regulated in the late 1970s and beyond.

The emissions just described are known as anthropogenic emissions, because they are basically man-made. There are also VOCs generated from biogenic sources, such as plants and animals. Not counting methane, biological sources emit an estimated 1,150 teragrams (approximately 1.27 billion short tons), of carbon per year in the form of VOCs.

The majority of VOCs are produced by plants, the main compound being isoprene. The remainder are produced by animals, microbes, and fungi such as molds. Of the total VOC concentration in the atmosphere, approximately 72 percent is from biogenic sources and 28 percent from anthropogenic sources. The major anthropogenic VOC emissions

are from on-road vehicles and industrial processes. Although biogenic and stationary sources comprise the majority of sectors producing VOC emissions, mobile-source VOC emissions are the focus of this article. Some VOCs are also considered mobile source air toxics (MSATs), another set of hazardous air pollutants.

VOCs combine with nitrogen oxides (NO_x) under sunlight to create ozone (O_3), one of six criteria pollutants regulated by the EPA under the Clean Air Act. Ozone contributes to what most people experience as “smog” or haze, which occurs most frequently in the summertime but can occur throughout the year in some southern and mountain regions. The highest ozone concentrations usually occur between 2 P.M. and 8 P.M. from May through September.

Most operating vehicles are powered by an internal combustion engine, in which burning fuel creates heat that ultimately propels the wheels supporting the vehicle. VOCs represent one type of emissions that are by-products of this combustion process. These emissions, which occur when the vehicle is operating, are known as tailpipe emissions. VOCs can also escape into the air through fuel evaporation, which can occur even when the vehicle is idling or parked. These emissions are known as evaporative emissions.

Health Impacts

VOCs can have harmful effects by themselves and also in combination with other pollutants. Exposure to air toxins such as VOCs can have cancerous and noncancerous health effects. Noncancerous health effects that can result from exposure include neurological, respiratory, liver, and kidney effects, as well as effects on the immune and reproductive system. People who live or work near major roads or spend a large amount of time in vehicles are likely to have higher exposures and higher risks. Further, people living in homes with attached garages are also likely to be exposed to benzene levels that are higher than average.

As described earlier, in sunlight and heat, VOCs combine with NO_x to create ozone, a criteria pollutant regulated under the Clean Air Act. Ground-level ozone can be harmful to one's health. Even relatively low levels of ozone can cause health effects.

Ground-level ozone can lower one's resistance to diseases such as colds and pneumonia. It can

also damage lung tissue, intensify heart and lung diseases (such as asthma), and cause coughing and throat irritation. Even healthy adults doing heavy exercise or manual labor outdoors may experience the unhealthy effects of ozone. People with lung disease, children, older adults, and people who are active outdoors may be particularly sensitive to high levels of ground-level ozone.

Children are at greatest risk from exposure to ozone because their lungs are still developing, and they are more likely to be active outdoors when ozone levels are high, which increases their exposure. Children are also more likely than adults to have asthma. Ozone can also affect sensitive vegetation and ecosystems, including forests, parks, wildlife refuges, and wilderness areas. In particular, ozone harms sensitive vegetation, including trees and plants during the growing season.

Recent Trends

VOC emissions from all sources decreased 63 percent from 1980 to 2010, and 35 percent from 2000 to 2010. In terms of actual tonnage of pollutants, between 1990 and 2010, total estimated VOC emissions produced nationally decreased by 52 percent, from 23 million tons to 11 million tons.

Looking at the emissions trends in terms of actual quantities, from 1980 to 2010 there has been a decline in total emissions of 177 tons (approximately 66 percent) from all criteria pollutants during that time period. Needless to say, whether it is through cleaner cars, stricter air quality controls, or the shift from a manufacturing to a service-based economy, America is making progress in addressing its overall air quality.

EPA has also instituted stricter regulations on the emissions and controls of MSATs. In February 2007, EPA finalized a rule, known as the Control of Hazardous Air Pollutants from Mobile Sources, to reduce hazardous air pollutants from mobile sources. The rule will limit the benzene content of gasoline and reduce toxic emissions from passenger vehicles and gas cans. EPA estimates that in 2030 this rule will reduce total emissions of VOC by over 1 million tons.

VOC Reduction/Control Strategies

As indicated in statistics cited above, there was a significant decrease in VOCs nationwide from 1980 to 2010. This can be attributed to many federal and

state regulations and control measures that have been implemented within the past several decades. Examples on the mobile side include the vehicle inspection and maintenance (I&M) programs in place in many states, cleaner (reformulated) gasoline, reduced fuel volatility, Stage II Vapor Recovery controls, low-sulfur gasoline, and transportation control measures (TCMs).

Inspection and Maintenance Programs

Vehicle inspection and maintenance programs (I/M) help improve air quality by identifying high-emitting vehicles in need of repair (through visual inspection, emissions testing, and/or the downloading of fault codes from a vehicle's onboard computer) and requiring them to be fixed as a prerequisite to vehicle registration within a nonattainment area. They are mandatory in many ozone nonattainment areas.

Successful implementation of I/M programs has led to a significant decrease in VOC emissions. In Illinois, the I/M program has led to a reduction of 26 tons per day of VOCs in northeastern Illinois, equivalent to the reduction of 650,000 cars per day or 375 medium-sized factories. Illinois's I/M program has also led to a reduction in benzene (among other air toxins) of 260 tons per year.

Reformulated Gasoline (Phase I and Phase II)

Most ozone nonattainment areas now require the use of reformulated gasoline. Reformulated gasoline (RFG) is gasoline blended to burn cleaner and reduce smog-forming and toxic pollutants in the air. Phase I of the reformulated gasoline program made great progress. Between 1995 and 1999, it cut smog-forming pollutant levels by about 17 percent compared to conventional gasoline in communities where 75 million people live and work.

Phase II of the program, which began January 1, 2000, took another step toward cleaner air. It reduces smog-forming pollutants 27 percent more than conventional gasoline. In addition to the federal requirements governing the use of reformulated gasoline, states can also adopt their own, stricter standards.

Reducing Fuel Volatility

Volatility is the property of a fuel that defines its evaporation characteristics. Reducing fuel volatility via the reduction of the Reid vapor pressure (RVP)

is another measure many states have implemented to reduce VOC emissions. At lower RVP values, gasoline evaporates less, thus releasing less VOC into the atmosphere. In certain ozone nonattainment areas, the EPA regulates the vapor pressure of gasoline sold at retail stations during the summer ozone season (June 1 to September 15) to reduce evaporative emissions from gasoline.

Stage II Vapor Recovery

Gasoline-dispensing pump vapor control devices, commonly referred to as Stage II Vapor Recovery Control, are systems that control VOC vapor releases during the refueling of motor vehicles. This process takes the vapors normally emitted directly into the atmosphere when pumping gas and recycles them back into the fuel storage tanks, preventing them from polluting the air. The Stage II system

controls the release of VOC, benzene, and toxics emitted from gasoline.

Low-Sulfur Gasoline

Another measure that has already been implemented and mandated by federal law is the requirement of using low-sulfur fuel. The EPA has issued proposed Tier 3 standards, which would set new vehicle emissions standards and lower the sulfur content in fuel from 30 parts per million (ppm) to 10 ppm, starting in 2017. These proposed standards would reduce both tailpipe and evaporative emissions (including VOCs), from passenger cars, light-duty trucks, medium-duty passenger vehicles, and some heavy-duty vehicles.

The National Association of Clean Air Agencies has estimated that full implementation of the Tier 3 standards and phaseout of the existing Tier

Pedestrians walk through heavy smog seen at street level in Beijing, China, in 2006. Volatile organic compounds (VOCs) combine with nitrogen oxides (NO_x) under sunlight to create ozone (O_3), contributing to smog or haze, which occurs most frequently in the summertime. Even relatively low levels of ozone can be harmful to one's health, causing coughing and throat irritation, damaging lung tissue, and worsening lung diseases such as asthma, as well as affecting the heart, liver, kidney, and brain.

2 standards could reduce VOC emissions 26 percent by 2030, equivalent to an absolute reduction of more than 250,000 tons.

Transportation Control Measures

Transportation control measures (TCMs) are methods of reducing VOC and NO_x emissions by decreasing vehicle miles traveled and improving traffic flow. Typical TCMs for a metropolitan area include a regional ridesharing program, park-and-ride stations, expanded and improved public transit, traffic flow improvements (as in signal synchronization), incentives for bicycles and pedestrians, and employer commute options, as in limiting parking or subsidizing transit for employees. Although these measures do not have as much direct impact on reducing VOC emissions as the other alternatives mentioned, they are relatively inexpensive to implement and have other benefits in addition to reducing VOCs.

Many VOCs have been reduced because of statewide and national regulations. For example, CFCs have been largely curtailed since the United States banned their use in 1978 and the signing of the Montreal Protocol in 1989, which called for the complete elimination of CFCs by 2000.

Conclusion

Ultimately, VOC emission reductions, as with any pollutant, require a combination of strategies, targeting both the on-road, off-road, and stationary sectors. Each of these control strategies will have some impact on reducing VOC emissions. If not known already, this is typically uncovered in the state implementation plan (SIP) development process, when states and regions are in the process of compiling emissions inventories to determine which sectors are contributing the most VOCs.

Walking

Walking is a very common type of low-impact aerobic physical activity. Because our ancestors often spent large portions of their days walking in pursuit of resources, our bodies have evolved in the expectation of frequent exercise. Recently, urbanization and specialization of labor have reduced the distances people need to travel to achieve various needs, while simultaneously innovating new means of transportation that do not require physical activity.

Today, walking is still very common, but the average number of steps taken in a day has dropped dramatically. Efforts to employ technology to avoid physical exertion in daily activities have become more and more artful, even as people simultaneously spend considerable effort to attempt to ward off obesity, leading to the common occurrence of people avoiding walking in daily life yet walking on a treadmill at the gym.

People walk for many reasons—for exercise, for transportation, or for the experience itself. Walking can help people maintain a healthy weight, improve balance and coordination, build healthy bones, manage stress and improve emotional well-being, and ward off or manage a range of health problems from diabetes and cardiovascular disease to cognitive decline.

Many people walk with children or animals to supervise them in getting exercise. The U.S. Centers

for Disease Control and Prevention guidelines recommend at least 150 minutes of moderate-intensity exercise, such as brisk walking, each week. However, most U.S. adults do not meet these guidelines.

Especially for short trips, walking is often a great way to get from one location to another within reasonable proximity, in which case walking may be called “active transport.” Taking a stroll can also be very pleasant. Research has found that being near natural scenes and living green environments fosters mental health, stress reduction, and alertness.

Walking can be a form of meditation, including in Zen Buddhist practice. In contrast to most types of mechanized transit, walking allows people to fit into smaller spaces, avoid collisions, and does not require much infrastructure or equipment. Thus, walking can be egalitarian.

Because foot travel allows unplanned deviations and direct physical experience of a place, pedestrians often are more aware of the places they traverse. Whether in urban or rural areas, then, walking can allow interactions such as picking flowers, greeting casual acquaintances, or reading bulletin boards.

These casual interactions might seem unimportant, but researchers believe they help communities build “social capital,” a store of social interactions and expectations that can promote positive action toward shared goals. For instance, bystanders may prevent crime, neighbors may band together to fight against a common problem, and a positive

sense of community may help reduce stress. That is, as more people walk, walking becomes safer for everyone. This “mass effect” is particularly beneficial for those who must walk and thus benefit the most from “eyes on the street.”

Likewise, as more people use public transit, which often involves some walking, too, public transit systems become more financially viable and are able to offer more services. Walking in a place increases knowledge of and emotional investment in the locale, and this sense of community may encourage people not to move out, and to come up with plans to improve the community. The existence of places where many people gather to stroll can be crucial to businesses that rely on “foot traffic”—customers who may not seek out a particular product or service but may be enticed to consume by what they see when they pass by.

Equity Issues

In many places, it is not uncommon to see advantaged locals driving, while disadvantaged residents walk for transport. This image underscores the potential for inequality in transportation, especially given that roads are typically supported by taxes, but car ownership can be an additional price needed to take advantage of roads.

This equity issue becomes even more poignant in areas where public transit is not available and road-sides are not designed to be safe for pedestrians or cyclists because they lack sidewalks, pedestrian overpasses, and car barriers. Not only those who cannot afford vehicles but also children and people with physical limitations experience mobility limitations in car-centered environments.

Adolescents may face additional barriers to walking when their parents’ safety concerns keep them near home, which can be particularly problematic when those safety concerns are unfounded and have the perverse effect of promoting obesity and social isolation.

These aspects of walking provide the potential for a political dimension. Walking takes place in physical space, and this physical space is also social space. Crossing a legal boundary is called “trespassing,” but sometimes walking leads to trespass of merely social boundaries that are nonetheless deeply felt. In this way, walking is often a very different social experience depending on who is walking and where.

Some (often affluent) communities have put in place design features, including fences with gates, that effectively block outsiders from passing. Many racial minorities, people without fixed home addresses, or members of other marginalized groups have experienced harsh words, police action, or violence simply for being in (often public) places from which others wish to exclude them.

Walking can also be an exercise of the power of mass unity, as in street protests, or when employees “walk out” of their workplace in pursuit of shared goals. Another way walking reveals power dynamics is through the experiences of those who are not able to walk the same way others can. Architectural elements such as stairs, curbs, and rough pathways may make navigation very difficult for disabled or elderly people. Many places now have laws—in addition to the federal Americans with Disabilities Act—that require inclusive designs such as ramps.

Actually, the physical environment people live in tends to influence walking behavior for everyone, researchers think. The places people live, work, learn, and play, both those that seem natural and those constructed, have all been changed by human influence. These human habitats are called “the built environment,” a material space reflecting and influencing cultural norms and practices.

Recent Research

A great deal of research in the last 10 years has found that people who live in places with certain design features are more likely to walk, and more frequently. Specifically, there is good evidence that walking for transportation is more common where people live closer together, distance to nonresidential destinations is short, and there are more different types of places nearby (that is, a more diverse land use mix).

There is also some evidence that a more connected street network (such that walking distances are shorter) encourages walking, that parks and open space facilitate walking, and that people avoid walking where they do not feel safe. Many of these ideas have been crystallized into an urban planning paradigm called “new urbanism.” New urbanism encourages urban design standards, such as transit-oriented development (TOD) and neotraditional neighborhood design. Some critics, in fact, view new urbanism as almost “romanticizing” walking.

One challenge in this research agenda is that people who want to walk may choose to live in places where walking is easier. This phenomenon—in which a behavior correlated with a predictor appears to be caused by the predictor but may not be—is called selection (in this case, residential selection). Recent research has focused on determining whether and how the physical features of a place actually directly cause changes in travel behavior or physical activity. This is because the standard of evidence required for changes in government policy ought to be high, particularly since built environment infrastructure is often expensive.

The goal of this policy-oriented research is to suggest how to design better urban planning policies that can promote healthy physical activity, reduce vehicle emissions and fossil fuel consumption, and avert traffic accidents by promoting walking. The goal is to encourage walking in a population, which could help reduce rates of obesity, cardiovascular disease, depression, and other health problems. One irony here is that because walking routes tend to be near roadways, pedestrians can be exposed to higher levels of vehicular and other air pollution while walking than if they were traveling inside cars.

During the 20th century, federal (i.e., the Federal Highway Administration) and state funding was poured into large transportation projects that encouraged construction of highways. Major road construction influenced walking behavior by promoting car ownership and because the roads sometimes served as effective barriers to pedestrians. Some recent initiatives to invest in alternative transportation methods include the Intermodal Surface Transportation Efficiency Act (1991), the Transportation Equity Act for the 21st Century (1998), and the 2005 Safe, Accountable, Flexible, Efficient Transportation Equity Act: A Legacy for Users (SAFETEA-LU). These policies have restored incentives and funding for alternative transit, but many still believe that U.S. transportation policy is heavily focused on automotive transit.

Trying to change this trend, some public health advocates have fostered a set of policy initiatives centering on how children get to school. These initiatives attempt to engage parents and schools in creating opportunities for walking and address obstacles to walking, such as fear of crime, traffic danger, and lack of knowledge. For instance, national Walk to

School Days promote walking by making it a community activity and highlighting safe routes.

In the United States, younger adults are rumored to increasingly value an active lifestyle and the ability to walk to work or commercial destinations. This can be a challenge, because U.S. design has been characterized as extremely “automobile-dependent.”

When residential areas are distant from commercial destinations and workplaces, residential lots are large, highways are common, and roads are not very interconnected, this land use pattern has been called “sprawl.” U.S. suburbs and newer cities tend to sprawl.

As the population continues to increase, demand for housing increases. Jobs also shift locations, influencing which cities grow (and shrink). Thus, the future of urban character in the United States and elsewhere is at stake as cities make decisions about how to change and evolve. It is likely that urban form may become more walkable as land values increase, and that walkable areas will rebound in terms of economic valuation, further encouraging demand for walkable areas.

Will the urban form become more walkable? Will Americans take to walking longer distances, and more often? These questions, still unanswered, are important for future population well-being, as well as for the transportation industry.

Water Pollution

Water pollution occurs when there is any chemical, biological, or physical change in the quality of a body of water that poses a potential detrimental effect for the plants, animals, and humans that use it.

The main source of water pollution comes from human activities. The damaging activities can be divided into two main sources. The first includes activities that result in the discharge of pollutants at specific locations through pipelines or sewers directly into a body of water, such as the operations of some industrial factories, sewage treatment plants, natural resource mines, and agricultural businesses. The second main source of water pollution is categorized as being nonpoint sources, which are those that cannot be tracked to a single site of discharge. Examples include acid rain, groundwater contamination, and traffic impact.

As transportation activities have increased to support growing demand for passenger and freight mobility, the resulting traffic volumes and ramifications have had negative impacts on water quality in the United States. The Clean Water Act (CWA), established in 1948 and expanded in 1972, outlines the basic structure for regulating discharges of pollutants into U.S. waters and sets quality standards for contaminants in surface waters across the nation. The U.S. Environmental Protection Agency (EPA) is responsible for enforcing the CWA regulations.

Contamination From Transportation

Transportation activities exert significant influence on water conditions and quality. Emissions associated with marine transport represent the most direct source of water quality impact from the transportation sector. The main impact of marine transport operations on water quality derives from dredging, waste, ballast waters, and oil spills.

Dredging involves deepening harbor channels by removing sediment from the floor of the water bed. While the process is critical for creating and maintaining sufficient water depth for shipping operations and port accessibility, it also has a negative outcome for the marine environment. Specifically, dredging stirs up sediment that modifies the water's properties and biological diversity if not subject to decontamination techniques.

Waste generated by the operations of transport vessels at sea or ports can contain high levels of

bacteria that could cause serious environmental and health problems when discharged directly into waters. Furthermore, waste that is not easily biodegradable can linger on the water's surface for long periods of time and impede maritime navigation, especially inland.

Ballast waters are required to control a ship's stability and to account for variances in weight distribution in cargo being transported. Ballast waters acquired in one region may contain non-native species or bacteria that become invasive and destructive when released into a new marine environment. Finally, oil spills from cargo vessel accidents represent one of the most serious problems of pollution from maritime transport activities.

In addition to direct water pollution from maritime transportation activities, there is a tremendous amount of fuel, chemicals, and other hazardous particulates discarded as by-products from airplanes, automobiles, railroads, and port operations every day around the globe. The pollution from sulfuric and nitric acid deposits dispersed into the air, for example, is concentrated by atmospheric conditions and returns to Earth in the form of acid rain.

Acid rains result in increased acidity in still bodies of water such as lakes and wreak havoc on their ecosystem balance. Add to that the dirt, dust, road salt, antifreeze, engine oil, rubber and metal deposits, and other common pollutants found in runoff from roads, bridges, parking lots, and other impermeable transportation surfaces and the upshot is an onslaught of transportation-related pollutants flowing into aquifers, lakes, rivers, streams, and oceans. As a consequence, water chemistry, quality, and habitat are constantly being degraded.

Further contamination of groundwater can be attributed to leaching problems from underground gasoline storage tanks used to support the transportation industry. Similarly, the need to transport millions of gallons of oil each year to serve expanding transportation needs has led to thousands of environmentally damaging marine and surface oil spills each year. Even when there are no accidents during the transport of oil, coal, or other mineral products, the transportation vessels must be cleaned after delivery. That process leads to substantial amounts of pollutants being discharged directly into international waters, causing considerable disruption and potential damage to marine life.

A crewmember stands by while an officer with the U.S. Coast Guard takes samples of ballast water from a ship before it enters the Great Lakes near Montreal, Canada, on June 3, 2008. Ballast water can carry bacteria as well as non-native species, and inspections such as these are mandated to help reduce the introduction of invasive species into the Great Lakes.

The construction and maintenance of transportation infrastructure additionally contributes to water pollution, especially but not exclusively in cases where infrastructure and facilities are erected and operate near aquatic ecosystems.

Storm Water Pollution

Storm water pollution is a serious concern. It results from materials and chemicals—such as used oil, detergent, and dirty water from washing a car—that are swept into storm drains from streets, gutters, parking lots, construction sites, industrial sites, and neighborhoods. Storm water pollution is significant because, unlike the household water that passes down a sink drain or toilet, storm water is left untreated and is carried through municipal water lines and deposited directly into lakes, rivers, streams, bays, or the ocean. Likewise, any material or chemical that is left on the ground can wind up being washed down a gutter and transported into the closest body of water.

Storm water systems were originally designed to swiftly direct rainwater off roadways during heavy storms. However, the same systems also carry pollutants ranging from motor oil to food packaging to construction waste through the streets and into waterways.

Used oil from just one vehicle oil change can contaminate a volume of up to one million gallons of freshwater, making it a significant contributor to storm water pollution. One EPA estimate pegged used oil contamination in the United States as being nearly the equivalent of 17 *ExxonValdez* spills each year.

Even seemingly innocuous materials, such as biodegradable cleansers used to wash one's car, can pose significant problems for fish and other life supported by aquatic habitats if they end up in storm water systems. Contaminated storm water also can be detrimental to human health and recreation. For example, as polluted water makes its

way to the oceans, water quality can be affected to a point where beaches are deemed unhealthy and are closed to human use. Polluted storm water may also carry bacteria and viruses that could cause health problems in humans who swim in it, including earaches, sinus problems, diarrhea, fever, and rashes.

Approaches for Water Cleanup

The best approach to cleaning up contaminated surface water is to prevent additional discharges from contaminated sources. By stemming further damage, the water's natural biological, chemical, and physical processes may be able to break down and eliminate the existing contamination.

In bodies of water where natural processes are insufficient to dissolve the contaminants, other cleanup approaches, such as manual mixing and aeration, may be needed. Contaminated sediments typically contain persistent contaminants that are difficult to resolve and may require removal by dredging, confinement by covering, or patience to allow natural processes to eventually cover the sediment or break the contaminants down over time. For contamination that does not integrate with the surface water and instead floats on the surface, which is common in oil spills, the contamination usually can be removed by skimming it from the surface.

The EPA and its state and territorial partners have developed a range of cleanup programs designed to evaluate and, when necessary, execute cleanup of contaminated sites. The cleanup efforts are conducted by the EPA, other federal agencies, state or municipal governments, and/or the parties deemed responsible for the contamination. In cases where oil or hazardous chemicals have contaminated the environment, the EPA has ultimate responsibility for overseeing the investigation and cleanup efforts.

The Superfund cleanup process is initiated when there is a possible hazardous materials contamination. Using the steps outlined in Superfund, the EPA makes a preliminary assessment and site inspection, ranks the site on the Hazardous Ranking Systems National Priorities List, conducts a remedial investigation and feasibility study to understand the nature and extent of contamination, determines which cleanup methods will be used, and creates a remedial design and action plan. Once cleanup is completed, the EPA oversees ongoing operation and maintenance of the polluted site to ensure effectiveness of the remediation effort.

The EPA's Federal Facilities Restoration and Reuse Office works with other agencies to clean up past pollution such as environmental contamination, hazardous and radioactive waste, munitions and explosives, and toxic substances. Similarly, the EPA's Brownfields and Land Revitalization efforts balance the protection of human health and the environment with needs for redevelopment.

The federal Underground Storage Tank (UST) Cleanup program addresses UST leakages, which seep into the soil and contaminate groundwater used for drinking and surface water used for transportation and other human activities. The EPA also works to prepare for and respond to oil spills affecting the country's inland waterways through its Spill Prevention Control and Countermeasure program (SPCC). The agency indicates that the program has helped reduce the number of oil spills to less than 1 percent of the total volume of oil handled annually.

Enforcement for oil cleanups is provided under the Oil Pollution and Clean Water Acts. Regulatory enforcement encompasses administrative and judicial penalty actions for oil spills, SPCC program violations, and other regulatory requirements.

Welfare Reform

When Bill Clinton ran for president in 1992, one of his campaign pledges was to change the nature of welfare. He proposed reform in 1994 but it was defeated in Congress. In 1996, Republicans put forth a proposal that was passed and signed into law by President Clinton.

That welfare reform act was the Personal Responsibility and Work Opportunity Reconciliation Act of 1996. The aim of the legislation was to move people from a dependence on welfare to working. People were limited as to the time they could receive welfare benefits.

States were given the funds and responsibility for moving people into the workforce. Among the many barriers to people being able to join the workforce was the issue of transportation. Many of those moving from welfare to jobs were faced with the challenge of being able to get reliable transportation to and from their work sites.

Often fathers and mothers had the additional transportation challenge of dropping children off at a child care facility on the way to work and then picking the children up on the way home. The federal government encouraged states to work toward providing transportation alternatives for those in need. States were allowed to use funds provided by the federal government to develop plans and to provide transportation for those transitioning into the job force.

The welfare reform legislation of 1996 created a program titled Temporary Assistance for Needy Families (TANF). This program replaced the Aid to Families with Dependent Children (AFDC) program that had provided welfare payments to families with children. The new program provided for TANF block grants to be made to states, which would have control over the expenditure of those funds within general guidelines.

Some funds were also made available to local government organizations, Indian tribes, and certain other organizations that were tasked with helping move welfare recipients into the workforce. The block grants were for the purpose of providing for individuals as they moved away from welfare and to employment.

The federal legislation provided that individuals could receive payments for only 24 months at a time and that an individual could only receive TANF

payments for 60 months during his or her lifetime. Some states provided for even shorter maximum payment periods. To receive TANF funds, individuals had to go to work, be looking for work, or be preparing for work.

States were encouraged to move individuals to the workforce through target goals set by the federal government. The federal goal was that 50 percent of single-parent family recipients receiving TANF benefits should be involved in work activities. Work activities would include, among other activities, subsidized or unsubsidized work, some educational activities, approved community service involvement, and job searching.

Not all work-related activities were equal. For instance, searching for a job could count for only short periods of time. Among TANF benefits to individuals were direct payments, help with child-care expenses, and help with the expenses for transportation related to work. TANF benefits were a part of the safety net that provided for those in most desperate financial need.

The work requirement is almost supreme in the welfare-to-work system administered primarily by states. There are a number of significant barriers that welfare beneficiaries must overcome if they are to go to work. Among these barriers are lack of education, young children to take care of, lack of role models with good jobs, a poor economy, lack of jobs, lack of job skills and work experience, poor health, substance abuse, domestic abuse, and lack of understanding of workplace practices that are necessary to keep a job. An example of the latter factor is lack of understanding of the need for punctuality. Another major factor is the inability to get to the work site due to lack of transportation.

Transportation

As opposed to the general population, a higher percentage of welfare recipients do not own cars. This lack of independence in transportation contributes to the difficulty of being able to get to a work site in a reasonable length of time. Even with employment, low-income workers may not be able to afford a vehicle and the costs of fuel, insurance, upkeep, taxes, and fees that are inherent in ownership.

Where public transportation is available, the disadvantage is not as severe, but there can still be problems. A significant percentage of welfare recipients live in the central core of cities, but jobs have

often moved from this part of the city to the suburban parts of the metropolitan area. Public transportation is often not particularly reliable in providing dependable transit to the suburbs from the cities, known as reverse commuting. This is especially true when there is no regional transit system and when one must transfer from one system to another. This can add expense and time to the trip to and from work in the suburbs.

Those living in rural areas may face the need to travel nearer to cities to find work because of the paucity of jobs in less densely populated environs. Public transit is seldom available in these rural areas.

Even the cost of good public transit—where it is available—can be prohibitive for someone who is living on the financial edge. The need for help with transportation is largely dependent on how accessible jobs are from the neighborhood where the welfare recipient lives. Also, welfare recipients are likely to get hired in entry-level jobs requiring night and weekend hours when public transit is even more difficult to access. Those in need, maybe for the first time, of public transportation services may not yet have the skills for interpreting bus schedules and routes, especially if transfers are needed.

Transportation Aid

The Transportation Equity Act for the 21st Century (TEA-21), enacted in 1998, was comprehensive federal legislation dealing with a wide variety of transportation needs in the country. It impacted the welfare-to-work transportation issue by creating the Job Access and Reverse Commute (JARC) Grants program. This was a four-year program funded initially through 2003.

The program's purpose was to make grants primarily for mass transit initiatives designed to provide transportation for welfare recipients to and from their work. The focus was also on the development of transportation opportunities to suburban work sites for those who lived in cities, rural areas, and the suburbs. TEA-21 also enabled states to place welfare recipients in training toward employment as skilled highway construction workers. This training was accompanied by support programs that would lead to a greater likelihood of long-term employment, including help with child care expenses and work transportation.

The process of providing transportation aid to low-income individuals who are seeking to move

from welfare to work is complex, and agents in a wide variety of roles must work together if workable solutions are to be found. It is important to note that there is no one solution to the transportation needs of individuals in diverse settings and with diverse backgrounds.

Three separate groups that must absolutely work in tandem are organizations, public or private, providing transportation services; social service providers, especially those dealing with TANF benefits and services; and employers and those working to provide jobs.

Transportation providers are familiar with the issues of providing transit but may not have great familiarity with TANF requirements or with the job situations that those returning to the force face. Each group has its special set of responsibilities. This can lead to a difficult working relationship with the other entities.

The transit company, for example, may not like being told that additional services are needed. Employment entities may not like suggestions that they should provide transportation late at night for their employees who have no cars and are unable to use public transportation. Social service entities may often not like the demands made on them to provide additional funds to develop additional avenues of public or private transit. All this requires a collaborative planning process. The federal government has encouraged the various entities to work closely together for the benefit of those in need of transportation.

Collaborative planning and the work of individual partners in the process have resulted in a great variety of solutions to the transportation needs of former welfare recipients. Not every one of these will work in every setting. There are many variables that can make one plan work better than another in any particular setting.

One solution that has been implemented has been modifying bus routes and schedules to meet the schedules and work sites of those entering the workforce. Another tool has been the use of shuttles or other ways to provide services that may be impractical for a large public bus to provide. These shuttles could be coordinated by various entities interested in providing help, including public transit agencies, faith-based groups, or employers.

Special late-night services have been developed in some locations. Some groups have brought in

a coordinator to help provide for transportation needs. These individuals may work with a variety of transportation formats to provide a customized plan for recipients with various needs.

Carpooling and ridesharing have been encouraged in some settings. A number of plans have been developed to get automobiles into the hands of those needing transportation. A variety of approaches have been used. Sometimes, recipients are sold a car by the social service agency and payments made to the agency go into a pool to be used to replace the cars.

The automobiles are often obtained from government surpluses. Funds have been used to enable former recipients to set up their own transportation companies that provide rides for people moving into the workforce. Subsidies have also been provided to riders to help them pay for public transit fares. There have been additional plans that provided rides for the children of workers to their child care centers.

Information is also provided to riders so that they can understand the transportation system. This includes multilingual materials. All planning should continue to address unmet needs. As people move, as jobs locations shift, and as population centers migrate, there will be a continued need to address transportation needs of those transitioning into the job force.

Wildlife Crossings and Barriers

As road construction continues to increase around the world, automobiles are frequently placed in competition with wildlife that historically has occupied or migrated through regions now crossed by roads. This endangers not only the wildlife but also humans. For instance, automobile collisions with large animals may result in injuries or fatalities to the automobile's occupants, not to mention damage to the automobile itself. Construction of underpasses and overpasses for the use of wildlife, referred to collectively as wildlife crossings, is one approach used by transportation ecologists (also called road ecologists) to help solve this problem. However, because the construction of wildlife crossings adds to the cost of road construction, transportation ecologists are concerned not only with establishing the effectiveness of this approach, but also with finding the best ways to build crossings in terms of siting, design, and other aspects.

Background

The practice of constructing wildlife crossings to mitigate the harm caused by road construction is fairly recent in the history of transportation; the first wildlife crossing, an underpass for black bears, was built in 1955 in Florida. The first European wildlife crossing was built in 1974 in the Netherlands; it was a tunnel constructed for badgers. In 1982, Canada built its first wildlife crossing, the Trans-Canada Highway wildlife underpass in Banff National Park, consisting of about 20 underpasses and overpasses, intended for use by many species including bears, wolves, moose, and elk.

The Intermodal Surface Transportation Efficiency Act (ISTEA), a U.S. federal law passed in 1991, included funds for preventing damage to wildlife habitat and thus encouraged construction of wildlife crossings. Today, the longest wildlife overpass in the world is the *Natuurbrug Zanderij Crailoo*; over half a mile (800 meters) long and 54 yards (50 meters) wide, it is located in the Netherlands, which has over other 600 wildlife crossings as well.

Despite this progress, the interaction of humans and wildlife on roads continues to pose a threat to both. According to the Federal Highway

This fencing under construction in April 2012 was part of a new wildlife barrier design intended to direct deer away from unsafe crossings of U.S. Route 97 in central Oregon.

Administration, in the United States alone, millions of vertebrates are killed annually through vehicle collisions, and over 200 motorists die each year in vehicle-animal collisions, with thousands more injured.

Loss of habitat also poses a severe threat to some types of wildlife: for instance, the grizzly bear now occupies less than 2 percent of its former range, and the red-legged frog is no longer found in 99 percent of its former habitat in Canada. A third problem is habitat fragmentation as wildlife populations are divided into smaller, isolated units, increasing their susceptibility to inbreeding and genetic defects, as well as increasing the probability of their extinction from natural causes.

Effectiveness

Researchers studied the effectiveness of wildlife underpasses and fencing to protect white-tailed deer after construction of a 15-mile (24.1 kilometer [km]), four-lane divided highway through forested

and agricultural areas in rural North Carolina. Three wildlife underpasses combined with fencing were included in the road's construction, with the fencing used to guide the deer to the underpasses.

Data was collected from a 10.7-mile (17.3 km) segment of this new road before and after construction, using two actively triggered camera systems (set up so that the camera recorded an event if an infrared beam was interrupted, as by an animal passing through it) at each underpass site, and also by track analysis, identifying species that crossed an 8-foot (2.5-meter) track pad the width of each underpass.

The combination of fencing and underpasses proved generally effective not only for the white-tailed deer, which were the focus of the project, but for other species as well. An average of 6.7 times more deer per day were observed at each of the monitoring sites after construction of the underpasses as opposed to before, suggesting that the fencing was successfully "herding" them to the underpasses.

Most (93 percent judging by camera recordings, 88 percent by track analysis) of the animals using the crossings were deer, but other species, including raccoons, Virginia opossums, American black bears, bobcats, great blue herons, unidentified snakes, and unidentified turtles were also observed using the underpasses (no species other than deer was recorded at the crossings in the pre-construction phase). Wildlife mortality was lowest in the areas closest to the underpasses, but a surprising number of deer were killed while crossing just past the end of the fencing, suggesting that they followed the fence to its end, but in the direction away from the underpass; for this reason, the authors suggested that fencing should be continuous between underpasses.

Another research group studied factors associated with the use of wildlife crossings along a 16.8-mile (27 km) stretch of State Road 260 in central Arizona. In the studied area, before construction of the crossings, motorists experienced about 36 collisions per year with large wildlife, mainly elk.

Seventeen wildlife crossings (11 underpasses and 6 bridges) were included in a reconstruction project for the road between 2000 and 2010. Researchers used animal-triggered video surveillance systems to record the use of the crossings by wildlife and calculated both the number of approaches (coming into

the area but not using the crossing) and successful crossings, finding that 72.4 percent of approaches resulted in successful crossings.

Many species were recorded using the crossings, including black bears, mountain lions, raccoons, and coyotes, but the most common large ungulates (hoofed mammals) recorded were elk (68 percent) and white-tailed deer (13 percent), so only those species were included in a multiple regression analysis to identify factors associated with crossing use. For elk, in the first year of data collection, season, time of day, crossing structure, and months monitored helped predict a successful crossing, but by the fourth year of the study, only the structure of the crossing was significant.

In addition, the probability of a successful crossing increased over the four years of the study, suggesting that the elk learned the location of the crossings over time. For deer, only crossing structure was significant, and that effect held true over all four years of the study. The authors suggest that crossings should not be placed in areas with frequent human activity, should provide cover at the entrances, and should not be built with walls that harm visibility and provide ledges for predators.

Women in Transportation

Women tend to be underrepresented in the transportation industry in most countries, especially in management positions and in some traditionally male-oriented professions. This phenomenon is partly linked to broad economic, social, and cultural factors affecting the full participation of women in the job market, and to barriers restricting their opportunities in technical and operational professions. Women working in the industry may also face challenges not faced by male colleagues, such as discrimination both on the job and outside work.

Public policies have increasingly addressed the issue of women in the sector, given the increased political focus on the provision of equal opportunities for all and the realization that the low participation of women in business organizations leads to efficiency losses. Private companies and professional organizations have also led initiatives to promote gender equality in the industry.

In the United States, according to the Bureau of Labor Statistics, only 15.9 percent of the full-time workforce in transportation and material moving occupations were female in 2012, while in the total labor force of the country, the proportion of women was 47 percent.

The European Foundation for the Improvement of Living and Working Conditions reports values of 25 percent and 30.9 percent for the proportions of women in the transportation and communications sector in western and central/eastern Europe, respectively. In developed countries with a

traditionally low proportion of females in the workforce, such as Japan, and in the developing world, the underrepresentation of women in the industry is even more conspicuous than in the United States and Europe.

As in other sectors of the economy, the underrepresentation of women in transportation is especially noticeable in management positions (15.6 percent in the United States). The proportion of women is also low in technical and operational positions. Only customer service positions show proportions of women similar (or in some countries, slightly higher) than proportions of men. Gender-based segregation is also pronounced in professions traditionally dominated by men.

In the United States, professions in the industry with a very small percentage of women include truck drivers (5.4 percent), railroad conductors (5.6 percent), and aircraft pilots (4.1 percent). In most professions, women are particularly under-represented in older age groups. Statistics in some regions of the world, such as in Europe and Australia, also suggest that the proportion of women in many professions seems to be stagnating during the last decade.

Barriers to Participation

The low participation of women in the transportation industry may be partly explained by broader social issues restricting women's employment prospects. For economic, social, and cultural reasons, women often have more demanding space and time restrictions than men, because they are often responsible for tasks such as child care, elder care, shopping, and domestic chores.

The work-life balance is therefore more difficult to manage for women than for men. The issue is especially relevant in the case of jobs in public transportation, because of a high prevalence of shift and night work. The job security of women is also often at risk before and after childbirth, while the right to maternal leave or child care leave is not universal, even when enshrined in the law.

Barriers are also posed to women at the level of recruiting, because they may be faced with intrusive questions not usually asked men regarding age and marital status, which may be used to discriminate in the selection of job candidates.

Other social and cultural issues may explain women's underrepresentation in some professions in the industry. For example, the gender imbalance

in the case of science and engineering jobs may be linked to the lower proportion of women having the required skills, such as mathematics and physics. This fact is, in turn, explained by the traditionally low proportion of women studying in technical universities.

Other professions, such as bus drivers and conductors, may show a gender imbalance because women are at a higher risk than men in terms of personal safety on the job, especially in night buses.

The representation of women in job advertising may also be biased and lead to gender segregation within the industry, because women are more often portrayed as service providers than as technicians, especially in the case of public transportation. Despite the relevance of these social and cultural factors, there is little research on their specific role in shaping women's career choices in the sector, because they also depend on personal preferences.

As in most sectors of the economy, women working in transportation also tend to be at a disadvantage in terms of average earnings. This pattern is mainly explained by their higher relative concentration in lower-paying jobs and by limitations on the opportunities for promotion. The International Transportation Workers' Federation reports that in most countries, women have lower rates of membership in trade unions, leading to lesser power in voicing their specific views.

Women in the transportation industry may also experience discrimination on the job. Discrimination may start at the level of recruiting, because women can be assessed in terms of physical appearance to a higher degree than men, especially in industries such as aviation or in professions such as customer service.

Isolation can also occur because of the minority position of women in a male environment, along with working cultures that may alienate women. The work environment itself may also be hostile because of such factors as the need to wear uniforms that were originally designed for men's bodies, or the lack of female toilets in the workplace. Women may also experience discrimination in the larger society because of stereotypes and prejudices against women employed in some jobs, such as truck drivers.

Efficiency Gains

The gender imbalance in the transportation industry is increasingly relevant in terms of public policy,

in light of recent studies showing that increasing the diversity in a business organization lead to gains in efficiency. For example, a report by Catalyst (a nonprofit organization focusing on women in the business world) shows that the companies in the Fortune 500 group with more female board members tend to show the best performances.

There are also reasons to believe that women can bring unique inputs to organizations in the transportation industry. For example, surveys of practitioners and researchers in the field have shown that women seem to attach more importance than men to the social dimensions of transportation projects, such as the effects in terms of the social inclusion of the populations affected.

Because women are currently underrepresented in managerial positions, women's perspectives on the use of public transportation may also be underrepresented in decisions. As such, an increase in women's share in those positions could have synergic effects in gender equality.

Studies on the role of women in the transportation sector, such as the European Project Wise (Women Employment in Urban Public Transport), have also mentioned the benefits of the communicative qualities of women in administration and customer service.

Legislation

The employment prospects for women in the transportation industry have benefited in recent decades from general equal opportunity employment laws. These policies emphasize the need for equal access to employment and seek to eliminate gender-based discrimination in recruitment and in the workplace.

The issue of establishing mandatory quotas for women is more controversial, and although it has been subject to regular public discussion in several countries, it has rarely been included in equal opportunity laws. Nevertheless, larger companies may set their own targets. Equal opportunity laws also set minimum requirements for the length, timing, and payment of maternity leave.

Despite the advances in this type of legislation around the world, in many developing countries, women are still at a considerable disadvantage in their access to jobs in this sector. This is mainly because transportation firms in these countries operate in a largely informal market, especially in

A U.S. Fish and Wildlife Service worker drives heavy equipment in a national wildlife refuge. While the overall U.S. workforce was 47 percent female in 2012, the full-time transportation and material moving workforce was only 15.9 female.

the case of urban public transport, which tends to be provided by a large number of minibus companies.

In addition, given the informal character of the business and of some of the outer urban areas crossed by these buses, female workers may be at risk of sexual abuse, especially in the cases of night travel. Women are also more exposed than men to harassment from passengers frustrated with poor levels of service.

However, government-led programs have been used to attract women to the transportation industry. In the United States, the Federal Highway Administration (FHWA) and U.S. Department of Transportation (USDOT) provide training, scholarships, and internships to improve the skills of women and other groups underrepresented in the transportation sector. A long-running example

of these projects is the Summer Transportation Internship Program for Diverse Groups, which offers opportunities for field work and work experience for students in transport companies.

Private Sector Initiatives

Initiatives in the private sector have also been important in the quest for increasing the participation of women in the industry, and many of the larger employers now have equal employment policies. Some common measures have the objective of reconciling work hours with women's time restrictions. These include part-time work, flexible working hours, and work-from-home options.

The scope for implementation of these measures is varied. Smaller companies or companies with only a small number of female employees may not have the flexibility required to implement them. The provision of conditions for maternal leave may also be part of the company's equality program, while larger companies may also provide facilities such as kindergartens.

Other initiatives aimed at increasing the attractiveness of transportation jobs for women include job regulations and education regarding sexual harassment between colleagues and, in the case of jobs in services like public transport, a firm stance against harassment from passengers.

Professional organizations have also led an active role in the promotion of professional development for women in the industry by organizing courses and offering scholarships and opportunities for networking. One example is Women in Transportation, an international network of women in the public and private transportation sector that organizes mentoring and leadership training programs.

Workers unions, such as the International Transportation Workers' Federation, have also worked to solve challenges faced by women in the transportation industry, highlighting the specific barriers posed to women in different countries and providing forums for the exchange of experiences.

Women's Issues/ Gender Issues

Among women, there are highly important individual distinctions that depend upon location, income, age, household, elder- and child-care responsibilities, ethnicity, employment status, degree of disability, class, and education. Notwithstanding such variety, there are significant differences between the transport needs, travel behaviors and patterns, and levels of physical access to work, services, and recreation of women compared to men. Gender-based transport differences tend to be more accentuated in developing countries.

A gender analysis of transport systems seeks to reveal these differences in particular contexts. It also seeks to uncover potentially detrimental effects proposed transport programs or projects might have on women and men.

The benefits of this type of analysis include (1) higher economic rates of return on infrastructure investment and higher profitability of mass transport systems; (2) better responsiveness to user demand; (3) lower transaction costs because of system optimization for both genders; and (4) improved access to employment, education, and services for men and women, which ultimately raise productivity and strengthen the household economic base.

Gender issues, including gender equality, gender equity, and gender mainstreaming or gender

integration, have become important in transport, as well as other policy areas.

Gender terms are defined as follows: (1) gender equality refers to the equal rights, responsibilities, and opportunities for women and men; (2) gender equity is the process of being fair to women and men (by including affirmative action, which compensates for historical and social disadvantages); and (3) gender mainstreaming or gender integration is the process of ensuring that gender perspectives are central to all activities, including policy development, research, advocacy/dialogue, legislation, and resource allocation, as well as planning, implementation, and evaluation of transport programs and projects.

Travel Behavior and Patterns

Women, especially in urban areas, tend to take more trips at shorter distances and more varied times than men. More of their trips are associated with their domestic work in maintaining the household, while more of men's trips are work related. Women's trips are costlier in terms of time and money (because they tend to make multiple stops and pay multiple fares).

Because women are more likely to be employed part-time and/or in the informal sector, and to be making social visits to families and friends, their destinations are less concentrated in a few main areas (for example, the central business district). They tend to make more off-peak trips, traveling to more dispersed locations, while most transit service is planned around the typical workday commuting patterns and concentrates on a few major routes.

Women are more likely to "trip chain," which means having multiple stopovers during a trip (for example, on the way to work they might stop at a day care center or a market). Women combine domestic-related trips together to make them more affordable or to link them to a work-related trip. For this reason, women tend to value flexibility over time savings in their travel choices. Frequently, women forgo opportunities to work outside their neighborhoods if they perceive transport services to be unreliable and fares to be expensive.

Men tend to have much more linear origin-destination trips centered on employment. In transport, men tend to value speed, reliability, and road safety. Because income-generating trips are more valued than domestic trips, vehicle use (car, motorcycle,

bicycle, and transit) is higher for men. Also, men generally use motorized modes more than women.

Female trip chaining is not considered in most urban transport system designs. However, there are some exceptions. Metro systems in many east Asian cities cater to busy female commuters by providing grocery and convenience stores, as well as child care, within station buildings. In many cities in south Asia, rickshaws are a popular low-cost, reliable, flexible, door-to-door means of transport, which enables women to travel without being harassed or feeling uncomfortable in overcrowded buses and using inadequate sidewalks.

Travel requirements vary based on household composition (that is, in female-headed households, the woman is responsible for both domestic and income-producing activities and the children bear more responsibility within the household).

Income levels are another factor that affects travel. In both developed and developing countries, gender-based differences are generally less pronounced among the very rich (who can afford private cars) and the very poor. Cultural factors, including religious behavior such as prayer or worship, influence travel behavior as well. While generally women travel more than men, men travel more than women in later stages of life and in Islamic cities.

Public Transport Services

Men and women have different expectations of and experiences with public transport (buses, trams, metros, paratransit, taxis, and trains). As mentioned, women are more likely to travel at off-peak hours; therefore, they prefer a more flexible service.

More often than men, women carry children or shopping bags when utilizing mass transit. Deep steps, onboard ticketing, and lack of room for strollers and shopping carts make it difficult for them to easily enter and exit transit vehicles. To address some of these issues, modern transit systems (including bus systems) offer prepaid, on-level boarding at stations.

In most places, policies exist for passengers to give up their seats to pregnant women or women with young children. Some countries, such as the United Kingdom, employ transport "gender audits" of their public transport systems.

Men have less aversion to overcrowding in public transport vehicles, which for women is a major

security issue because crowding facilitates groping and inappropriate behavior. Also, having generally smaller stature and less physical strength, women are more uncomfortable in overcrowded vehicles, with passengers pushing each other while boarding and alighting.

More often than men, women meet with discrimination in transport services on the part of drivers and ticket collectors (for example, denied boarding or overcharged). Also, women are disinclined to travel in insecure environments, such as taking a bus at night or a taxi alone.

In terms of the unhealthy consequences of transport systems, men are more exposed to air and noise pollution because of the fact that most operators of transit and paratransit vehicles are male.

Private Vehicle Ownership and Use

Typically, men have priority to use a vehicle in a household, and when possible to motorize, while women use the vehicle that is left behind (for example, bicycles when men move to motorcycles, motorcycles when men move to cars). This might be

explained by the fact that a higher value is attached to income-generating trips, and men are more likely to be employed or earn higher income.

Patriarchy is another explanation. Men, with a traditional position of superior power within the household hierarchy, are considered more entitled to appropriate the most efficient means of transport.

Female automobile ownership rates (and also the degree to which women obtain a driver's license) are disproportionately low, even in wealthier countries. (The United States is one of the few countries where this is not the case.) This partly reflects their lack of money to afford to buy vehicles or pay for services. The lack of access to motorized vehicles tends to exacerbate the persistent economic inferiority of women.

Increasingly, women are using bicycles for travel. In some countries (for example, Japan and the Netherlands), the bicycle industry has developed specialized vehicles for women (for example, lightweight, equipped with grocery baskets and/or child seats). On the other hand, in many parts of Africa men are opposed the idea of women cycling.

A commuter stands beside a subway platform sign designating the location of a women-only car available during rush hours in the Rio de Janeiro, Brazil, metro system in January 2013. Women-only subway and train cars, which can provide greater security and protection from harassment, have been introduced in several other countries, including Japan, India, and Mexico.

However, this resistance often decreases if women's economic productivity increases through the use of a bicycle.

Safety and Security

The term *safety* implies road safety, while the term *security* implies perception of danger from crime, violence, and harassment. Although both are matters of concern for both sexes, men tend to be more concerned about safety and women more concerned about security. However, women's safety concerns are higher in relation to nonmotorized than motorized transport (for example, women are less likely to use a bicycle without the provision of bike lanes).

In terms of road safety, more men than women are involved in road crashes. Worldwide, death and injury rates resulting from traffic accidents are four to five times higher for men than women.

In terms of security, women are more vulnerable users of public space and public transport vehicles. Women who carry packages or children, and therefore have their hands full, are targeted and become easy prey of pickpocketing. Because of the fact that they can be overpowered by aggressors (typically men), women's physical safety is threatened as well. On public transport vehicles, women are exposed to verbal harassment by drivers, collectors, or other passengers if wearing short skirts, shorts, or tight clothes. They are also victims of fondling and touching by men, as well as, on rare occasions, physical assault and rape.

Because of security issues, women are often forced to change their transport behavior, thus limiting their transport options. For example, women might decide (1) not to travel at night; (2) not to get out at particular stations, thus lengthening their travel time; (3) to take a longer route home if it is safer; (4) to wear only "appropriate" clothing when walking after dark or using public transportation; (5) to travel in groups, possibly including men; (6) to only board public transport units that are not full; (7) to carry self-defense items; and (8) to stand against a window or at the back of the public transport vehicle.

To deal with security issues affecting women, several cities have instituted gender-targeted policies such as "stops between stops" (Montreal) for women to get off a bus at a between-stops location closer to their destination, "women-only train

carriages" (Tokyo, Mexico City), and "women-only buses" (Dhaka, Bangladesh, a service later found to be unaffordable for most women).

However, general improvements to transport systems, such as good lighting in public transport stations and vehicles, are important enhancers to women's perception of security.

Work Zone Traffic Control

Work zone traffic safety issues derive from the pervasive number of extensive highway construction and reconstruction projects that are ongoing at any time in every state around the United States. Dangerous conditions lead to high-risk situations because of such varied factors as excessive driving speed, less-than-ideal visual clues, less-than-high alertness, and low levels of comprehension by drivers of the risks involved in work zones.

To meet and answer these challenges, there has been a growing body of research, analysis, and policy development to improve the approaches used by construction management and law enforcement bodies to enhance control of work zone traffic.

Efforts to directly improve work zone traffic control on the roadways include driver education, visual signals, electronic communication, and law enforcement activity.

Driver Education

The plethora of media channels available to improve driver awareness of highway work zone safety issues is an ongoing opportunity as well as a challenge because messages can be diluted if they are not properly targeted and received in an appropriate context by the driving public.

The most appropriate environment for speaking directly to drivers is at the various physical contact points that provide reasonable assurance that individuals are aware of traffic safety and driving behavior information. These contact points include both the physical locations and online manifestations of such places as motor vehicle registry offices, police stations and auxiliary facilities, health care clinics and offices, driver education classes in public and private schools, driver training schools, automobile dealerships, automobile repair shops, and the commercial and institutional headquarters of trucking and bus operators.

Visual Signals

A range of signage motifs and symbols have been tested over the years to alert drivers to construction hazards they are approaching. These continue to be refined. Categories of such signals are diverse. Some are strictly concerned with notifying drivers about approaching lane changes or lane closures. Others focus on explicit speed limit reduction in work zones; many such signs include warning messages about increased fines for speed violations committed in work zones. Still other signs appeal to drivers' empathy with the workers on the road, for example, the "Give 'em a Brake" motif.

Electronic Communication

Increasingly, state highway departments are deploying illuminated signs on roadways that can be updated from centralized and regionalized transportation department control bases. The signs

are positioned as permanent installations on overpasses or purpose-built sign rigs, or, alternately, are positioned as mobile, self-powered units.

In either case, wireless links to transportation authorities permit the display of succinct messages to alert drivers of actual and anticipated work zone traffic situations miles ahead of the work site, giving drivers time to modify their driving behavior on the highway and also to make decisions on alternate routes that may be present.

An adjunct to these standing signs are the mobile modes of personal communications that are available. Highway authority radio dispatches tend to suffer from the limited range of their radio broadcasting, but these projects could improve by uploading their content in podcast form and linking to cell phone and wireless Internet service provider networks.

Some authorities have already deployed mobile apps suitable for a variety of popular mobile device platforms. Real-time video imagery of major interchanges, for example, can be displayed, along with graphic indications or text and tabular displays notifying motorists of work zones in their area.

Law Enforcement Units

Most jurisdictions have come to rely on the physical presence of law enforcement units as the most effective means of assuring better work zone traffic control and safety. However, there is great divergence in the types and intensity of deployment. A typical technique is the positioning of an officer and marked vehicle adjacent to the travel lanes within or upstream of a work zone.

There are choices made by law enforcement officers as to specific operating procedures. Whenever the emphasis is on active identification and citation of traffic law violators, for instance, the officer can operate either overtly in full view of approaching traffic, or adopt a covert strategy from an unmarked vehicle or an out-of-view vehicle position.

If the primary goal is to alert approaching drivers and calm traffic flow in the work zone, the officer and marked vehicle are positioned close to the travel lanes, typically with emergency lights flashing.

Driver Reactions

Research has shown that in order to be motivated to modify their behavior, drivers must perceive a threat of apprehension by law enforcement in order

for the presence of law enforcement in the work zone to be effective.

Driver behavior analysis reveals at least three criteria in the driver's thought process that determine this effect and influence his or her reaction. In some manner or another, the driver must be convinced that there is a significant law enforcement presence. Therefore, any given police unit (1) must be readily visible, (2) must be readily identifiable, and (3) must appear to be prepared for action.

An additional factor in driver perception and motivation to modify behavior is the density of law enforcement units in and around a given work zone. For example, any one police unit, if stationary, is visible to a given driver for only a short time. If the unit is moving with traffic, then it is visible to only a limited number of drivers. By increasing the number of units on hand, more drivers will see a police unit, and will see one or more for a longer period of time. The multiplying effect of law enforcement unit density can be quite significant when it comes to affecting driver behavior in and around a work zone.

A stationary enforcement vehicle and officer will tend to create a greater speed reduction than circulating patrols—but this effect will be localized. Specifically, speeds will be reduced from just before passing the unit to approximately one mile beyond where the unit is located. Therefore, a short distance, for example, approximately 1,000 feet upstream of where the speed reduction is most needed, would be a good position for the law enforcement unit.

On average, speed reductions on high-speed roadways tend to be in the five- to seven-miles per hour (mph) range. Depending on configuration of the road and other factors, however, there can be as much as a 14 mph speed reduction.

Additional Options

According to the National Cooperative Highway Research Program (NCHRP), some of the most effective variations on law enforcement deployment for work zone traffic control include the following measures:

- Stationing police upstream with flashing lights for a lane closure or full road closure on high-speed roads
- Temporary full highway closure (in one or both directions) by patrol cars to provide safe clearance to construction support

vehicles for installing lane closure barriers and markers

- Rolling roadblocks by patrol cars for the same purpose, or to shift traffic between divided-highway sides
- Secondary positioning of a supplemental patrol unit, typically downstream of the work zone, with radar support, to actively interdict and issue citations for traffic speed offenders

These measures, used separately and in conjunction, have been shown to effectively increase the credibility of work zone traffic control efforts in the perception of the driving public.

The NCHRP also has done extensive work in calculating the costs involved in deploying law enforcement officers and vehicles in support of and to direct work zone traffic control. This work has included such variables as overtime pay—and drop-off in effectiveness of personnel—for night deployments.

NCHRP analysis has examined a variety of funding mechanisms and channels for local and state transportation departments to consider. These include program-wide funding, project-by-project funding, and tapping revenues generated from citations issued in work zones.

Just as the nature and intensity of work zone traffic control modes themselves vary, the advantages and disadvantages of these three main funding approaches are applied in a patchwork manner across the country. Some aspects require special state legislative approval (for example, the use of work zone citation revenue to defray work zone enforcement). Other aspects are more administration-heavy, thus sapping a large portion of the funds they are meant to generate or acquire. It seems likely this range of options, rather than any one universal template, will remain the state of enforcement and revenue methodology for some time to come.

Automated Adaptations

Transportation departments in a small number of states now utilize some form of automated or semi-automated speed enforcement technology, which has shown promise as a very cost-effective manner of helping reduce traffic speed in work zones. Deployments of automated units in Maryland, Washington State, and Illinois capture speed data, along with visual evidence of the driver's license

plate, location, and date. In semiautomated deployments, an officer must be present on the scene to verify all data. In other jurisdictions, fully automated systems are permissible.

This tactic has proven effective, in some cases generating substantial revenues to offset other work zone traffic control measures. However, jurisdictions must first invest in the somewhat expensive equipment, supplies, and systems. These initial cost barriers, along with the necessity to amend standing state ordinances, have kept more states from automated or semiautomated system adoption—even those states where similar technology has long been in use to issue citations for red light violations. It is hoped that as the hard costs of such systems are reduced through innovation and defrayed by federal subsidy, the benefits can be harvested by more state transportation departments.

World Container Ports

Around 90 percent of all goods traded internationally are transported by ships at some point. Increasing, global demand for raw materials such as oil, metals and food, together with the rapid expansion of manufacturing industries in developing countries such as China and other southeast Asian states, has resulted in rapid growth in the volume of goods transported by sea.

Demand in the United States and Europe for cheap electronics, clothing, cars, and other products from those countries has also contributed to that growth. The top three trade routes for container shipping all originate from Greater China, which includes Hong Kong and Taiwan.

Those routes transport goods to the United States, to Europe, and to "Other" Asia (including all of Asia and Australasia but excluding Greater China, South Korea, and Japan), according to the World Shipping Council (WSC). WSC data also indicate that 10 of the top 20 container ports by volume are located in Greater China. The United Nations estimates indicate that container port throughput grew sixfold in the 20-year period ending in 2010, while WSC statistics show the global container fleet increased from just over 11 million units in 2003 to over 17 million units in 2009.

In order to transport goods in a secure manner and to speed up the whole journey from point of origin to final destination, containers were developed that can be stacked in large numbers on ships and are easily transferrable onto road or rail transport once a ship has arrived at a container port.

The development of shipping containers in the mid-1950s and the subsequent growth in container ports have played a key role in the development of intermodal logistics networks, or global supply chains, which link maritime and land distribution of goods. It has also contributed to a move away from bulk cargo ships that transport only a single cargo type, often requiring a significant amount of time (potentially weeks) and high levels of manpower to be fully unloaded and then reloaded for the return voyage.

In contrast, today's containers can be offloaded by a single individual using a cargo crane or gantry in a very short period of time. Those containers can be immediately loaded for transport away from the port or stored safely within a secure area,

and ships can be quickly reloaded for their next journey.

Containerization has also led to more efficient use of the available space on ships, because multiple cargoes belonging to many different companies can be shipped at the same time. Containers can be used to transport cargo from a number of different sources in a single container, with that cargo only being separated upon arrival at a distribution hub in a destination country.

The increasing use of shipping containers has also led to increases in vessel size, with some ships being capable of carrying more than 16,000 containers on board, with the result that volumes of cargo previously transported by several ships can now be transported in a single voyage. This has also contributed to the need for larger ports and dock-side facilities.

Container Ports

Container ports are maritime (sea) ports where containers arriving by ships can be unloaded for onward transport by road, rail, and inland waterways, or vice versa. Upon arrival in port, containers are offloaded using cargo cranes or gantries and may be either immediately transferred for the next part of their journey or stored in a container terminal.

A container terminal is an area designated for the storage of cargo in containers and is normally accessible by truck, rail, or sea. Full containers can be picked up, dropped off, maintained, or stored in that area. Container yards—additional areas for the storage of empty containers—may also be located within the port, although these areas generally do not have direct access to transport links and containers may be left in them for long periods of time.

Industry statistics from the WSC indicate that, in 2011, 10 of the top 20 container ports in the world were located in Greater China, while another five ports were located in southeast Asia, three in Europe, and one each in the United States and the Middle East. That Middle East port is Jebel Ali in Dubai, which, although ranked only ninth in terms of volume of goods transported, is the world's largest port geographically with a land area of 52 square miles (134 square kilometers).

The top 20 ports worldwide are ranked in Table 1, adapted from the World Shipping Council table of the top 50 world container ports.

Table 1 Top 20 world container ports

Rank	Port and Country	Volume (million TEUs*)
1	Shanghai, China	31.74
2	Singapore, Singapore	29.94
3	Hong Kong, China	24.38
4	Shenzhen, China	22.57
5	Busan, South Korea	16.17
6	Ningbo-Zhoushan, China	14.27
7	Guangzhou Harbor, China	14.26
8	Qingdao, China	13.02
9	Jebel Ali, Dubai, UAE	13.01
10	Rotterdam, Netherlands	11.88
11	Tianjin, China	11.59
12	Kaohsiung, Taiwan	9.64
13	Port Kelang, Malaysia	9.60
14	Hamburg, Germany	9.04
15	Antwerp, Belgium	8.66
16	Los Angeles, United States	7.94
17	Keihin Ports, Japan	7.64
18	Tanjung Pelepas, Malaysia	7.50
19	Xiamen, China	6.47
20	Dalian, China	6.40

*20-foot equivalent units.

Source: "Top 50 World Container Ports." World Shipping Council, 2013.

These rankings change on an annual basis, depending on volumes of trade annually, and so U.S. ports such as Long Beach and New York/New Jersey, which were ranked in the United Nations Conference on Trade and Development (UNCTAD) top 20 container terminals in 2010 (18th and 20th, respectively) are 21st and 25th on the WSC list in 2011. The ports ranked 17th and 20th in Table 1 did not appear in the UNCTAD top 20 in 2010. It is estimated that between 48 percent and 55 percent of global container traffic is handled by the top 20 container ports.

Shipping Containers

United Nations' statistics indicate that world container ports handled almost 337 million TEUs (20-foot equivalent units) of shipping containers through container ports in 2004, rising to over 531 million TEUs in 2010.

An aerial view of containers being transferred at a container port in Cape Town, South Africa, in 2008. Of goods traded internationally, about 90 percent travel by ship at some point.

Cargo volume and ship capacity are measured in TEUs, an industry standard reference set by the International Organization for Standardization (ISO) in 1961. This refers to the size of standard metal shipping containers (also known as intermodal containers, ISO containers, or shipping containers). TEUs are generally defined as measuring 20 feet long (6.1 meters) by 8 feet wide and high (2.44 meters), although heights can vary significantly, and are designed to be stacked on top of one another while being transported on ships.

While the length of containers can vary from the standard 20-foot container to as long as 53 feet (16.1 meters), the two most commonly used lengths and those defined as industry standards by the ISO are the TEU and the FEU (40-foot equivalent unit) containers. The latter is double the length of a TEU but is the same width. It is the most frequently used container because it can be loaded onto a semi-tractor-trailer truck for road transport.

Shipping containers, mainly built of steel or aluminum, are designed to be transferrable between ships, trains, and trucks without the need for the cargo to be unloaded at any point prior to its arrival

at its final delivery point. Containers can be fully enclosed or open sided, depending on what is to be transported inside them.

They can also be temperature controlled (known as a reefer container) when used to store fresh food or sensitive goods, to prevent deterioration of the cargo during its transportation. Increasingly, security of containers has been an issue and so special tamper-proof seals and Global Positioning System (GPS) monitoring is used to ensure they arrive at their destination with their contents intact.

Zero-Emission Vehicles

The term *zero-emission vehicle* (ZEV) came into common usage following the introduction of a landmark piece of legislation in California in 1990. The low emission vehicle (LEV) and Clean Fuels regulation was introduced by the California Air Resources Board (CARB) in September 1990.

One of the primary components to come out of the regulation was the zero-emission vehicle (ZEV) mandate. A relatively unknown concept before its introduction, promoting ZEVs through the mandate was seen as a bold policy, which subsequently became a very prominent and also controversial program. The ZEV mandate has come to be considered as a stand-alone policy, while other components of LEV regulation have progressed separately. The air pollution known as smog, experienced in Los Angeles and other large car-dominated cities in California, was the major driver for introducing the legislation. At the time of the regulation's introduction, efforts to alleviate the problems caused by the high numbers of cars on California's roads were primarily focused on delivering incremental improvements to the conventional internal combustion engine. But these were not producing sufficient results. With people driving farther and more often, and with more people opting for sport utility vehicles (SUVs) and light trucks, rather than standard passenger cars, the problems were worsening, not improving.

The ZEV mandate required a significant shift by requiring car companies that sold more than 35,000 vehicles in the state (at the time, this included General Motors, Ford, Chrysler, Toyota, Honda, and Nissan) to start offering products that did not produce criteria-pollutant tailpipe emissions. The actual definition of a ZEV, offered by CARB in 1990, was vehicles having “no evaporative emissions of any regulated pollutant.”

While not explicitly backing a particular technology at the time of the mandate, there were very limited ZEVs in production, or even in development. This meant that the initiative became focused on a particular technology that was the most advanced and capable of meeting the standards at the time—battery-powered electric vehicles.

This focus may have also stemmed in part from the announcement made by General Motors in 1990 that it was going to begin to commercialize electric vehicles, perhaps suggesting that developments would move quicker for this new vehicle technology than for the others. It actually transpired that hybrid electric vehicles (HEV) and biofuels became favored in the years following the introduction of the mandate, but they are not in its scope because they are not considered pure ZEVs.

The ZEV mandate required each of the large auto manufacturers operating in the state to derive 2 percent of their total annual sales from new vehicles between 1998 and 2000 from ZEVs; that 5 percent

One of the world's most successful zero-emission vehicles (ZEVs), the all-electric Nissan LEAF is seen here charging at an exhibition in June 2011. As of September 2013, a total of 83,000 Nissan LEAFs had been sold worldwide. The sixth version of the California ZEV mandate calls for the production of a total of 60,000 ZEVs from 2012 to 2017, and by 2025, the total ZEV fleet in California is expected to increase to around 1.4 million vehicles, with 250,000 produced in 2025 alone.

of new vehicles sold would be ZEVs in 2001 and 2002; and that from 2003 onward, 10 percent of the new car fleet would consist of ZEVs.

Unlike its predecessors, all of which attempted to address air pollution through so-called command and control measures (that is, forcing technological improvements through fining car companies for noncompliance with pollution levels), the Low Emission Vehicle and Clean Fuel regulation established a credit-based system. The premise of this program was that car companies that exceeded the targets in any given model year could accumulate credits, which could be saved and applied to total sales figures in later years or sold to competitors.

As well as minimizing the risks of investing in new, potentially unproven technologies for large manufacturers, the legislation provided a platform on which small and medium enterprises could also operate by specializing in LEV or ZEV models that

could be sold to larger companies unable to meet their targets. It was a most innovative approach at the time of its introduction.

While companies faced fines (mechanisms were in place for CARB to impose fines of up to \$5,000 for each violation on the manufacturer if it was more than a certain number of vehicles in excess of its quota), the premise was that the LEV program and the ZEV mandate were to be credit based to enable flexibility on the part of the manufacturers.

Amendments

From the introduction of the LEV program, CARB organized biennial reviews of the measures, including the ZEV mandate, to monitor progress against the objectives and ensure that the initiatives engaged relevant stakeholders in their evolution. Some intense policy debates played out in the early years, and, over time, it became clear that the

battery-focused technologies were not cost-effective nor were they performing against the air pollution objectives.

Therefore, since their introduction in 1990, the ZEV mandate rules have been altered several times; carmakers have continued to evade the challenge of delivering ZEVs, and, with changing market pressures and political and policy changes at the state and federal level, the mandate has been something of a moving target.

In 1996, CARB decided that because of the slow progress made in the development of ZEVs, the so-called ramp-up years (that is, the 1998 to 2000 and 2001 to 2002 targets) would be eliminated, leaving companies working toward the 10 percent target by 2003. In 2001, additional modifications were made that allowed the 10 percent target to be broken down further.

The large manufacturers were tasked with providing 2 percent pure ZEVs and 6 percent advanced-technology partial ZEVs, also known as PZEVs, which were to be based on technology designed to lead to ZEVs over time. However, in 2002, following a lawsuit, CARB was prohibited from enforcing the 2001 amendments for model years (MYs) 2002 and 2003.

More amendments followed in 2003, at which time litigation was brought to an end. These changes included pushing the implementation back to 2005. Following several years of review and consultation, CARB approved additional modifications to the mandate in 2008 and set about redesigning the program in 2009.

2017 to 2025 ZEV Mandate

The outcome of these processes—Advanced Clean Cars—was approved as a new emissions-control program for the period 2017 to 2025. This has brought the ZEV mandate in line with the national plan for vehicles, addressing both criteria air pollutants and greenhouse gas (GHG) emissions and the developments that had occurred in California relating to GHG emissions.

The 2017 to 2025 ZEV mandate is the sixth-generation package of measures to try to deliver a smog-free car fleet. From 2012 to 2017, the rules require the production of a total of 60,000 ZEVs, split between those manufacturers with the largest annual sales figures—Chrysler, Ford, General Motors, Honda, Nissan, and Toyota. Beginning in

2017, Audi, BMW, Hyundai, Kia, Mazda, Mercedes-Benz, and Volkswagen will all be expected to deliver against the new targets.

By 2025, the total ZEV fleet in California is expected to amount to somewhere around 1.4 million vehicles, with 250,000 produced in 2025 alone. If the rules are fully implemented by 2025, new cars will be 34 percent less GHG-intensive and emit 75 percent less smog-forming air pollutants.

They will not, however, have achieved the initial vision of the ZEV mandate, an increasing number of emissions-free vehicles over time. Indeed, since the first amendments in 1996, credit has been given to technologies that make conventional vehicles cleaner, with the division between pure ZEV and PZEV. Thus, the distinction that made the ZEV mandate unique to other efforts was removed, and ZEV became just another initiative designed to promote cleaner vehicles.

Assessment

As a result, the ZEV mandate has been heavily criticized. The development of hydrogen vehicles has been promoted at the state and federal level at various times since the introduction of the ZEV mandate, but this promising technology also remains on the periphery of the car market, challenged by the prohibitive research and development costs of scaling down the size of the fuel cell needed to produce the hydrogen often cited as the biggest barrier to mass delivery.

Despite its shortcomings and many critics' labeling the program a failure, there are also proponents of the role that the ZEV mandate has played in pushing progress on cleaner vehicles further than would have been achieved without the goal. And the importance of the ZEV mandate to the international vehicle fleet should also not be underestimated—not only because those car companies regulated in the state would have introduced lower-emission technologies to meet the standard into the global marketplace, but also because one in nine cars in America is sold in California. The state is responsible for some 4 percent of all vehicles sold globally, and so developments in California will continue to be an important driver of innovation and research and development as long as the need for cleaner vehicles remains.

There have also been important general lessons learned in California about the influence that

government can have over industry. Though it was an innovative approach, the ZEV mandates' changing goals and focus over the past 20 years have demonstrated that technology-forcing measures are very difficult to deliver and are unlikely to be accepted by industry. Ultimately, they are unlikely to succeed.

Nonetheless, measures that set particular standards and also offer flexibility about how those goals must be met have been proven in California and elsewhere to be favorable mechanisms for encouraging green technology. Although the ZEV mandate is falling short in terms of reducing air pollutants to the extent initially hoped, it has crafted a process through forward thinking that has potential to deliver results over the longer term.

Glossary of Terms and Acronyms

AADT: Average annual daily traffic, calculated by dividing the total traffic on a segment of highway over a year by the number of days in the year.

AADTT: Average annual daily truck traffic, a measure calculated by dividing the total volume of truck traffic on a segment of highway over the period of a year by the number of days in the year.

AAR: The Association of American Railroads, an industry organization including Amtrak (passenger rail) and the major U.S. freight railroads.

AASHTO: American Association of State Highway and Transportation Officials, a nonprofit association representing departments of transportation and highway departments in U.S. states, Puerto Rico, and Washington, D.C., with the primary purpose of fostering the development of an integrated system of transportation across the country.

AATF: The Airport and Airway Trust Fund, a fund created in 1970 by the federal Airport and Airway Revenue Act; the revenues come from taxes on users of the U.S. air system, including excise taxes on domestic passenger tickets, international passenger arrivals and departures, and cargo waybills and is used to maintain and expand airport facilities.

ABC classification: A method to classify goods (for instance, for inventory control) by splitting them into classes A (highest value), B (middle value), and C (lowest value); typically, A items are about 10 to 20 percent of the total count and 50 to 70 percent of the expected dollar value, the B group about 20 percent of both the count and the dollar value, and C items about 60 to 70 percent of the count and 10 to 30 percent of the value.

AC: Alcohol concentration, the concentration of alcohol in a person's blood (blood alcohol concentration [BAC]) or breath, used as a proxy for the person's level of intoxication and ability to safely operate a vehicle.

Accident: As defined by the U.S. Department of Transportation, an incident involving a moving vehicle, including collisions, derailments, and leaving the roadway, that produces unintended property damage, injury, or death; a collision of a vehicle with a person, if determined to be a suicide, is not classified as an accident.

Accounts payable: Sometimes abbreviated as A/P, the value of goods and services that have been received but have not been paid for.

Accounts receivable: Sometimes abbreviated as A/R, the values of goods and services that have

been shipped or rendered to a customer but for which the customer has not yet paid.

Ad valorem: A Latin phrase meaning *according to value*; an *ad valorem* tax or duty is based on the value of the items in question.

ADA: Americans with Disabilities Act, a 1990 U.S. law prohibiting discrimination based on handicap or disability; certain accommodations must be made in public transportation to facilitate use by persons with handicaps or disabilities.

ADR: A European agreement known by the French name Accord européen relatif au transport international des marchandises dangereuses par route. It took effect in 1968 and was most recently amended in 2011, regulating the road transportation across national boundaries of dangerous goods.

AGVS: Automated guided vehicle system, a method of transporting materials by small carts that are controlled by computers as they move along a guideway.

Air cargo: Cargo (freight) that is shipped by air.

Aircraft accident: As defined by the U.S. Department of Transportation, an occurrence incidental to flight and which causes fatal or serious injury to one or more people or substantial damage to an aircraft incidental to the operation of an aircraft.

Airline Deregulation Act: A 1978 U.S. federal law that eliminated many regulatory functions of the Civil Aeronautics Board; as a result of the act, fares decreased on many popular routes, and the number of people traveling by air in the United States greatly increased; however, prices increased on some less popular routes.

Airplane: As defined by the U.S. Department of Transportation, a vehicle that is heavier than air, driven by an engine, with fixed wings, and that uses the dynamic reaction of air against its wings in order to remain in flight.

Airship: As defined by the U.S. Department of Transportation, a lighter-than-air vehicle that is driven by an engine and can be steered.

Alternative fuels: Fuels used to replace more conventional fuels commonly used in transportation, such as those derived from petroleum. As defined by the U.S. Energy Policy Act of 1992, alternative fuels include alcohols such as methanol, mixtures including at least 85 percent alcohol, compressed natural gas, hydrogen, liquid petroleum gas, electricity, and fuels derived from biological materials.

AMPO: The Association of Metropolitan Planning Organizations, a nonprofit U.S. organization offering its members technical assistance, communications, access to research and training, and other services.

Analysis of alternatives: A method of approaching an issue by looking at how the various components of a system work together and considering the impact, including costs and benefits, of various proposed changes to that system.

Antidumping duty: A duty placed on imported goods to protect domestic industries; it is imposed when an exporter charges less for exported goods than the usual price in their own domestic market (i.e., when the exporter is dumping cheap goods on another country and thus making it difficult for the industry in the receiving country to compete).

APS: Advanced planning and scheduling, a set of techniques used to optimize manufacturing and logistics operations; often APS is used to simulate the outcomes from different scenarios in order to select the best course of action.

Arterial: A road designated to provide high-volume and high-speed travel, primarily for through traffic; generally, arterials are protected by stop signs, traffic lights, and so on, to avoid the necessity of frequent stops by drivers on the arterial.

ASN: Advanced shipping notice, information sent to a customer about a shipment that has been sent, including the contents of the shipments, and possibly information such as the expected time of arrival and the carrier used.

Asphalt: A sticky petroleum product used in road construction, particularly as asphalt concrete; a

combination of asphalt with other materials such as sand or gravel.

AST&L: The American Society for Transportation and Logistics, an organization founded in 1946 for people working in the logistics and transportation professions and that began offering a certification program in 1948.

ATA: The American Trucking Associations, an organization founded in 1933 to represent the U.S. trucking industry; it was created by the merger of the American Highway Freight Association and the Federation Trucking Associations of America.

Attainment area: In the context of air pollution, a geographic area that has met specified standards, for example, those of the U.S. Clean Air Act, as opposed to a nonattainment area, which has not met those standards; attainment is calculated separately for each pollutant, so a region can be an attainment area for some pollutants and a nonattainment area for others.

Average passenger trip length: In bus and rail travel, a measure calculated by dividing the number of revenue passenger miles by the number of revenue passengers.

AWB: Air waybill, a bill of lading for goods shipped by air.

AWO: The American Waterways Operators, a trade association for operators of barges, towboats, and tugboats on U.S. inland waterways.

Backhaul: The return trip of a transportation vehicle from its original destination to its point of origin; a backhaul may include a full, partial, or empty load.

Barge: A vehicle for carrying cargo over water, usually on inland waterways; barges may or may not have their own propulsion systems and are usually open topped, although covered barges also exist.

Barrier to entry: Any factor that may make it difficult for competitors to enter a market, such as high cost of equipment that must be purchased before beginning operation.

Basing point pricing: A method of pricing the cost of transportation from a specific location in a zone, even if the shipment does not actually depart from that location.

BCP: Business continuity plan, a contingency plan for a business to continue operating despite disruptions such as a natural disaster or labor unrest.

Bill of lading: A legal document specifying the terms and conditions agreed upon by a shipper (such as a shipping line) and the shipper of goods, describing the goods carried and their destination; the bill of lading accompanies the goods and, when they are delivered, is signed by the receiver to signify that they have been received.

Bonded warehouse: A secure warehouse for storing goods until the appropriate revenue laws are observed, for example, duty is paid on the goods.

Bottleneck: A point in a system in which the speed of forward movement is limited by accidental or imposed constraints, for instance, a stretch of road that suddenly narrows or a point in a manufacturing process where production must be slowed because of the lack of an essential component.

Break bulk: A process in shipping in which a bulk load is separated into smaller individual shipments.

B2B: Business to business, companies who sell goods and services primarily to other businesses rather than directly to customers.

B2C: Business to consumer, companies who sell goods and services directly to consumers.

BTS: Bureau of Transportation Statistics, a U.S. federal bureau established in 1992 by the secretary of transportation, with the charge of collecting and analyzing information about transportation, with a particular focus on intermodal transportation.

Bulk cargo: Dry cargo such as grain or coal that is not packaged.

Bulk carrier: A ship designed to carry large quantities of bulk commodities such as oil, grain, or coal in specialized holds; some are designed to carry multiple bulk products, some only a particular product.

Bullwhip effect: A phenomenon in which a small change in demand results in a large change in supply, for instance, from a product being back-ordered to being held in excess; the bullwhip effect is caused by delays in communication and transportation up and down the supply chain.

Cable railway: A type of rail system in which an operator can attach or release a given car from a continuously moving cable.

CAFE: Corporate Average Fuel Economy Standards, a set of standards established by the U.S. federal government for automobile and truck manufacturers requiring that the fleets produced by each manufacturer meet a composite sales-weighted fuel economy standard.

CAPSTAN: Computer-aided planned stowage and networking, a method developed by Koku-mation AB and the Southern Africa Europe Container Service Ltd. to plan stowage on cargo ships.

Cargo airline: An airline that specializes in shipping air freight as opposed to passengers; examples include DHL and FedEx Express.

Carmack Amendment: In the United States, a 1906 amendment to the Interstate Commerce Act of 1887 that clarified the liability of a carrier if goods are damaged while being shipped across state lines.

Carnet: A customs document that allows someone to bring goods into a country without requiring that duty be paid, with the understanding that the goods will be used in the country and then removed; for instance, a person might be allowed to bring a car into a foreign country for their own transportation needs and would not have to pay duty as long as the person took the car when he or she left.

Carpool: A method of transportation in which several people travel together in a private vehicle on

a prescheduled trip to a prearranged destination, possibly sharing the cost and work of driving.

Cartel: A method of limiting competition in which a group of companies decide to cooperate with each other, for instance, by establishing a common price for their goods or services.

Center of gravity approach: A method of planning a supply chain so that distribution centers are located to minimize transportation costs between manufacturing facilities, distribution centers, and markets.

Certificate of origin: A customs document that specifies the location of origin (e.g., the country) of imported goods.

Charter bus: A bus that has been booked by a group of passengers for their exclusive use for a particular trip and for a preestablished price.

Civil Aeronautics Board (CAB): A U.S. government agency established in 1938 to control the aviation market, including specifying the number and type of planes to fly particular routes and the range of ticket prices; most CAB functions were eliminated in the Airline Deregulation Act of 1978, and the board was eliminated in 1985.

CMAQ: Congestion Mitigation and Air Quality Improvement Program, a U.S. federal program that funds projects intended to help meet air quality standards.

CO: Carbon monoxide, a pollutant gas comprised of one oxygen to one carbon atom; it is colorless, odorless, and highly toxic to human beings and is created as a by-product of incomplete combustion.

CO₂: Carbon dioxide, a gas comprised of two oxygen atoms to one carbon atom and which is colorless and odorless; under high compression, it becomes a liquid.

Coastal carrier: A water carrier (ship) that provides service to coastal ports; in the United States, these would include ports on the Gulf of Mexico and the Atlantic and Pacific oceans.

Combi aircraft: An aircraft designed to carry either cargo or passengers or both at the same time.

Commercial bus: A bus that carries passengers in return for specified fees, whether charter service (prebooked for a particular set of passengers) or regular route service (following a specified route and providing transportation along it to anyone who pays the fare).

Common carrier: A company providing transportation of goods and people to the public, does not discriminate against or provide special services to anyone, and is subject to regulation regarding rates, services, and liability.

Commute: A regular trip made between an individual's home and his or her school or workplace.

Compressed natural gas: Natural gas under high pressure so that it can be used as a fuel for vehicles.

COTD: Complete and on-time delivery; a measure of customer service, COTD signifies delivery of a given order in its entirety on or before the time promised.

Culvert: A pipe or other drain allowing water to flow under a road and possibly allowing the passage of wildlife as well.

Deadhead: Returning a vehicle from its destination to its point of origin without transporting a load during that trip.

DUI: Driving under the influence, a legal designation in the United States describing a person judged to be operating a motor vehicle under the influence of illegal drugs or alcohol.

EIS: Environmental Impact Statement, a type of report mandated in the United States for certain federally funded projects, which must specify the potential adverse effects of the project, including pollution, displacement, or disruption of people or communities, and harm to natural resources.

Elevated railway: A railway that operates on tracks above street level.

Energy efficiency: A measure of how efficiently a product (e.g., a car) produces desired outputs relative to inputs (e.g., miles the car can run per gallon of gasoline used).

Environmentally sensitive area: An area with natural resources whose destruction or degradation could have serious consequences; examples include sources of drinking water and the habitat of declining or unique species.

FAA: The Federal Aviation Administration, a U.S. federal entity now part of the Department of Transportation and charged with ensuring aviation safety while encouraging the development of the aviation system.

FHWA: The Federal Highway Administration, the part of the U.S. Department of Transportation charged with administering the Federal Aid Highway Program and the Federal Lands Highway Program.

Funicular: A type of cable railway used to move cars up and down a steep slope by means of a permanently attached cable and in which the weights of ascending and descending vehicles counterbalance one another.

Gasohol: A blend of gasoline and alcohol.

Grade separation: A method of road construction in which intersecting of roads or railroads occurs at different heights so that the traffic on one does not interfere with the traffic on the other.

Gross vehicle weight rating: In the context of truck transport, the maximum rated capacity of a vehicle, including cargo, the driver, passengers, equipment, and the vehicle itself.

Growth management: The use of regulations and planning in an urban area to limit urban sprawl and promote smart growth.

GVW: Gross vehicle weight, the combined weight of a vehicle and the freight it carries.

HOV lane: High occupancy vehicle lane, also known as a commuter lane; one or more lanes of

a highway reserved (possibly at only certain times) for vehicles carrying more than one passenger.

Infrastructure: Physical structure such as roads, railway lines, and bridges that support transportation and development.

Inland and coastal channels: A designation for waterways in the United States that are usable for commercial navigation, including the Mississippi River System, the Great Lakes, the New York State Barge Canal System, the Atlantic Intracoastal Waterway, and the Gulf Intracoastal Waterway, but excluding waterways in Alaska.

Interstate highway system: In the United States, a designated system of divided, limited-access highways of at least four lanes that connect major cities and industrial areas.

ISTEA: The Intermodal Surface Transportation Efficiency Act, a 1991 U.S. federal law that required the creation of regional and state long-term transportation plans, increased the role of regional planning commissions and the public, and increased highway and transportation funding.

LNG: Liquefied natural gas, natural gas that has been made liquid by being cooled to minus 260 degrees Fahrenheit at atmospheric pressure.

Local street: A street intended to provide access to adjacent properties, as opposed to an arterial.

Logistics: Methods of moving goods in an optimal manner, delivering the right amount of product to the right location at the right time and at the right price.

Maglev: A transportation system using magnetic levitation to guide and propel vehicles that are suspended above the tracks.

Monorail: A rail system based on a single rail rather than the dual rails common to most railroads.

MSA: Metropolitan Statistical Area, a designation used by the U.S. Office of Management and Budget including one or more urban areas and

surrounding territory, all of which form an essentially metropolitan area.

MSATs: Mobile Source Air Toxics, a group of 21 hazardous air pollutants identified by the U.S. Environmental Protection Agency as generated largely by transportation sources such as cars and trucks; examples of MSATs include benzene, acet-aldehyde, and formaldehyde.

NAAQS: National Ambient Air Quality Standards; standards set by the U.S. federal government specifying the allowable concentrations of six pollutants: carbon monoxide, lead, nitrogen dioxide, ozone, particulate matter, and sulfur dioxide.

NCHRP: National Cooperative Highway Research Program, a U.S. research, development, and technology transfer program administered by the Transportation Research Board of the National Academy of Sciences.

NEPA: National Environmental Policy Act, a 1969 U.S. federal law requiring that any project requiring federal approval or using federal funding consider the environmental effects of a proposed action and its alternatives.

New urbanism: An approach to planning cities or urban areas so they are compact and favor the use of bicycles, foot travel, and public transportation and in which mixed-use areas combining housing, commercial areas, and recreation areas are common.

NHTSA: The National Highway Traffic Safety Administration, created in the United States in 1972 to reduce the deaths and economic losses from highway automobile crashes and to create mileage standards for vehicles weighing less than 10,000 pounds.

No objection fee: A fee paid by a charter airline to a scheduled airline so that the scheduled airline will not protest operation of a charter flight; such a fee is considered a bribe in some countries but is common practice in others.

NO_x: Nitrogen oxides, such as nitric oxide (NO) and nitrogen dioxide (NO₂), that form a major

component of ozone and are produced during high-temperature combustion.

O₃: Ozone, a pollutant formed by three molecules of oxygen and formed by the combination of nitrogen oxides and volatile organic compounds in the presence of sunlight.

ODS: Operating differential subsidy, an amount paid by the U.S. federal government to American flag-carrier ships to help offset the higher operating costs of U.S. as opposed to foreign vessels.

Particulate matter: Pollutants consisting of solid particles and liquid droplets that can be suspended in the air and inhaled; coarse particulate matter is in the range of 10 to 2.5 microns in diameter, while fine particulate matter is less than 2.5 microns in diameter.

Port marks: Letters, numbers, and geometric symbols followed by the name of the port of destination that are placed on export shipments.

Reformulated gasoline: Gasoline designed to reduce pollutants generated as a by-product of combustion, such as including oxygenates and lowering the content of heavy hydrocarbons, olefins, and volatile components.

Riprap: Rock or concrete rubble used to protect shorelines, pilings, abutments, and so on from water erosion.

Semi: Also known as a semi-trailer, a truck trailer without a front axle and which is moved by being coupled to a road tractor.

Shared roadway: An automobile road with a marked bicycle route but without any physical separation of bicycles and automobiles.

Shipper carriers: Companies that own their own vehicle fleets to ship their goods; this is a common arrangement for groceries and big box retail stores.

Shipping conference: An agreement among multiple shipping companies to charge common rates and provide common terms to provide passenger or cargo service over specified routes.

Shipping lane: A mapped route on the ocean used by commercial ships to avoid hazardous areas.

Shipping manifest: A document that lists all the items contained in a shipment, along with the end destination of each and the total weight.

Smart growth: In urban development, a type of growth characterized by efficient land use, mixed-use development integrating housing, commercial development, and recreation, while at the same time preserving open spaces and natural areas; preservation of existing communities is often a consideration also.

Straphangers: Also known as NYPIRG Straphangers, a group founded in 1979 to represent the interests of people using the New York City subway system.

Streetcar: As defined by the U.S. Department of Transportation, a lightweight passenger railcar operating on fixed rails; streetcars may or may not have the right-of-way at intersections and may or may not be separated from other traffic.

Supply chain: The entirety of a manufacturing process, from the acquisition of raw materials to the delivery of finished products, including all the interchanges of materials and information required along the way.

Tanker: A ship designed to carry liquid bulk cargo such as oil.

Tare weight: The weight of an empty shipping container or vehicle.

Third party logistics provider: A company that provides logistics services for other companies, such as transportation, warehousing, and freight forwarding; sometimes abbreviated as 3PL.

Through bill of lading: A bill of lading that covers goods over a journey from origin to destination, including transfers from one carrier to another.

TOFC: Trailer on a flat car, also known as piggy-back, a method of transporting goods by carrying loaded trailers or railcars on a flatcar.

Ton: A measure of weight; a short ton is 2,000 pounds, a long ton 2,240 pounds, and a metric ton 2,204.68 pounds.

Traffic calming: The use of techniques to limit the speed of automobiles and to create safe and pleasant areas for pedestrians and cyclists; examples include the use of speed bumps, curb extensions, and pedestrian islands.

Transshipment: In international trade, transferring a shipment from one carrier (usually a ship) to another.

Tugboat: A powered vessel that is not used for transporting goods but for towing or pushing ships, barges, and rafts.

ULD: Unit load device, a freight container or pallet.

Underpass: A type of grade separation in which one road passes under a railway or another road.

Urban sprawl: A type of development characterized by low density, by isolation of housing from commercial and residential development, and that favors automobile travel rather than public transportation, walking, or cycling.

Viaduct: A bridge constructed to allow one road to pass over another road or over a railroad or valley.

Waybill: A document used in common carrier freight shipment that contains basic facts about the shipment, including origin, destination, and charges.

Wet lease: Renting an aircraft with the provision that the owner will provide fuel, the crew, and ground support equipment (as opposed to a dry lease, in which none of those things is provided by the owner).

Wind rose: A graphical representation of recorded wind speed and direction over a historical period in a particular location.

York-Antwerp Rules: An international code of rules governing shipping, first established in 1890 and amended in 1924 and 1950.

Table 1 Country comparison: Airports

This table gives the total number of airports or airfields recognizable from the air. The runway(s) may be paved (concrete or asphalt surfaces) or unpaved (grass, earth, sand, or gravel surfaces) and may include closed or abandoned installations. Airports or airfields that are no longer recognizable (overgrown, no facilities, etc.) are not included. Note that not all airports have accommodations for refueling, maintenance, or air traffic control.

Rank	Country	Airports	Rank	Country	Airports

Table 2 Country comparison: Railways

This table states the total route length of the railway network and of its component parts by gauge, which is the measure of the distance between the inner sides of the load-bearing rails. The four typical types of gauges are broad, standard, narrow, and dual. Other gauges are listed under note. Some 60 percent of the world's railways use the standard gauge of 1.4 meters (4.7 feet). Gauges vary by country and sometimes within countries. The choice of gauge during initial construction was mainly in response to local conditions and the intent of the builder. Narrow-gauge railways were cheaper to build and could negotiate sharper curves; broad-gauge railways gave greater stability and permitted higher speeds. Standard-gauge railways were a compromise between narrow and broad gauges.

Table 5 Country comparison: Merchant marine

Merchant marine may be defined as all ships engaged in the carriage of goods; or all commercial vessels (as opposed to all nonmilitary ships), which excludes tugs, fishing vessels, offshore oil rigs, etc.

Total includes the number of ships (1,000 GRT or over), total DWT for those ships, and total GRT for those ships. DWT or dead weight tonnage is the total weight of cargo, plus bunkers, stores, etc., that a ship can carry when immersed to the appropriate load line. GRT or gross register tonnage is a figure obtained by measuring the entire sheltered volume of a ship available for cargo and passengers and converting it to tons on the basis of 100 cubic feet per ton; there is no stable relationship between GRT and DWT.

Ships include barge carriers, bulk cargo ships, cargo ships, chemical tankers, combination bulk carriers, combination ore/oil carriers, container ships, liquefied gas tankers, livestock carriers, multifunctional large-load carriers, petroleum tankers, passenger ships, passenger/cargo ships, railcar carriers, refrigerated cargo ships, roll-on/roll-off cargo ships, short-sea passenger ships, specialized tankers, and vehicle carriers.

Worldwide Freight Carriers	1802
U.S. Trends	1807
Summary	1814
Supplemental Tables	1817

Introduction

To move large quantities of goods across the country and around the world, Americans depend on the Nation's freight transportation system—a vast network of roads, bridges, rail tracks, airports, seaports, navigable waterways, pipelines, and equipment. Today, U.S. households can buy fresh fruits and vegetables in mid-winter, expect fast and reliable next-day deliveries of Internet purchases, and use electronic appliances manufactured thousands of miles away, often in other countries. Because economic activities worldwide have become more integrated and globalized, more goods produced by U.S. factories and farms are bound for export, and imports originate from more than 200 countries. This pace of trade Americans have become accustomed to is made possible by the complex intermodal transportation network that blankets the country and links the United States with world markets.

The movement of international freight among nations relies on a complex array of long-distance transportation services. The process involves many participants, including shippers, commercial for-hire carriers, third-party logistics providers, and consignees. Moreover, global trade depends on seaport and airport services to move large volumes of merchandise over long distances via a variety of transportation modes. The interaction of these services and participants is vital to successful global trade.

In 2008, U.S. carriers received \$22 billion for commercial freight services provided to businesses in other countries. U.S. seaports and airports received \$36 billion for port services. U.S. firms paid \$45 billion to foreign carriers for freight services and \$27 billion to foreign ports for port services (USDOT BEA 2009).

ABOUT THIS REPORT

This report provides a snapshot of freight transportation activity from a global perspective, highlighting physical characteristics and industry output for the U.S. and other leading world economies. The report gives a broad overview of trends in the movement of international freight among the top 25 world economies, measured by 2008 gross domestic product (GDP). It presents recent statistics on freight activity by leading global ocean and air carriers, seaports, and airports engaged in international freight services.

The report also presents an overview of major trends in U.S. international goods trade, as well as trends in U.S. freight and port services. It further examines how U.S. international freight activities compare with those of the world's top economies. The report concludes with a brief discussion of the key factors that are driving change in U.S. and global merchandise trade and freight activities.

OVERVIEW

The United States has the largest freight transportation system in the world, an extensive physical network of infrastructure and entities that provide transportation services:

- 4 million miles of public roads,
- 140,000 miles of railroad tracks operated by freight carriers,
- 25,000 miles of navigable waterways,
- 9,800 coastal and inland waterway facilities, and
- 5,200 public-use airports (USDOT RITA BTS 2009a).

The U.S. transportation network serves more than 300 million people and 7.5 million business establishments across 3.8 million square miles of land. Moving raw materials and finished goods between production and consumption centers, this freight network is a vital component of commerce in the United States.

The United States is the world's largest economy and leading importing nation, accounting for 23 percent of world GDP and 13 percent of the value of world merchandise imports in 2008.¹ Before 2002, the United States was the world's largest merchandise exporter. Germany became the leading exporting nation that year, and China moved to the top position in 2008.²

Despite recent setbacks caused by the 2008 U.S. and global economic downturn, the movement of freight globally shows a long-term upward trend. From 1998 to 2008, world merchandise freight exports nearly tripled in value from \$5.4 trillion to \$16 trillion. During this period, U.S. freight exports doubled from \$682 billion to \$1.3 trillion (USDOC CB FTD 2009). The rising trend in world exports indicates the strong interconnectedness among countries and the increased globalization of economic activities that generate freight movements.

While virtually all countries export goods and the United States receives exports from more than 200 countries, the overwhelming majority of global exports are concentrated in only a few countries. In 2008, the concentration of world exports among the top trading nations was significant:

- more than half (51 percent) of the exports were from 10 countries,
- three-quarters (76 percent) were from 25 countries, and
- about 91 percent were from the top 50 countries.

¹ This report analyzes trends in U.S. and global international merchandise trade and freight in terms of value because aggregate data for both exports and imports by weight are not available for all modes of transportation.

² In this report, China refers to the People's Republic of China. Data for Hong Kong are reported separately.

OVERALL TRENDS

Freight is generated by economic activity and the freight industry tends to respond to fluctuations in this activity and the resultant level of trade among nations. The 2008 global economic downturn caused by the collapse of major financial markets resulted in declines in U.S. merchandise trade with partners around the world. From mid-2008 to early 2009, as the U.S. and global economies struggled, world trade sagged and the movement of international goods by service providers slowed. By the second quarter of 2009, demand for U.S. and global freight shipments had plummeted. Financial liquidity problems and fluctuations in energy prices affected all modes of freight transportation and all sectors of the freight industry.

Before 2008, the global freight industry's primary challenge was growth in merchandise trade and the freight flows that strained system capacity. In 2009, declines in freight flows transformed the major challenge into the management of excess capacity. Shippers, carriers, and facility operators in the United States and around the world were forced to contract their freight operations in response to reduced trade volumes. By the end of September 2009, an estimated 548 container vessels with a carrying capacity of 1.3 million 20-foot equivalent units (TEUs) were idled at seaports worldwide as a result of the decline in global demand for containership services (AXS-Alphaliner 2009a).

The slowdown in economic activity in the United States and globally in 2008 and the subsequent reduction in U.S. consumer demand also affected international air cargo traffic and capacity. Global international air cargo, measured in freight ton-kilometers, fell 23 percent from 2007 (IATA 2009a).³ During the second half of 2008, air carriers around the world struggled with excess capacity and lower revenues. In particular, carriers were negatively affected by global reductions in oil prices. In principle, declining oil prices should have resulted in lower fuel costs for the airlines, but fuel-hedging contracts taken out at the start of the year when prices were much higher resulted in unexpected financial losses (IATA 2009a).⁴ By mid-2009, overall demand for air cargo and maritime freight had slowed because of weak economic activity and distressed financial markets.

³ This report uses metric ton-kilometers instead of ton-miles to describe trends in air cargo because it is the standard industry unit of measure when comparing air freight activity among countries. Most countries report their air cargo data in metric ton-kilometers.

⁴ Fuel hedging can negatively impact an airline if the price of jet fuel falls below the contracted price for future fuel deliveries, forcing the carrier to compete with those airlines purchasing fuel at the market rate. By mid-2008, crude oil sold for about \$140 a barrel. Prices declined to less than \$50 a barrel by end of the year as global economic activities slowed. Consequently, carriers who hedged in anticipation of higher prices recorded major losses in the fourth quarter of 2008.

Figure 1. Value of World Goods Exports by Country: 2008

SOURCES: U.S. Department of Transportation, Research and Innovative Technology Administration, Bureau of Transportation Statistics, based on data from various sources. **United States**—U.S. Department of Commerce, U.S. Census Bureau, Foreign Trade Division, available at www.census.gov/foreign-trade/www as of May 12, 2009. **World**—International Monetary Fund, Direction of Trade Statistics. Available at www.imfstatistics.org/dot/ as of Sept. 14, 2009.

- The global freight transportation infrastructure handles large volumes of cargo. In 2008, more than \$16 trillion of exported freight was transported worldwide. Maritime vessels, airplanes, trucks, and trains transported these goods from production centers to consumption markets.
- In 2008, the top three global merchandise exporters—China, Germany, and the United States—accounted for 26 percent of the value of total worldwide freight exports.

Figure 2. Goods Exports From Top Economies and Percent Share to the United States: 2008

SOURCES: U.S. Department of Transportation, Research and Innovative Technology Administration, Bureau of Transportation Statistics, based on data from various sources. **United States**—U.S. Department of Commerce, U.S. Census Bureau, Foreign Trade Division, available at www.census.gov/foreign-trade/www as of May 12, 2009. **World**—International Monetary Fund, Direction of Trade Statistics. Available at www.imfstatistics.org/dot/ as of Sept. 14, 2009.

- In 2008, about 13 percent of world freight exports from more than 200 countries (\$2.1 trillion out of \$16 trillion) were bound for the United States. Of this amount, 55 percent was oceanborne cargo, 20 percent was air cargo, and about 25 percent was carried by land modes of transportation (USDOT CB FTD 2009).
- For the United States' top three trading partners, the proportion of their exports bound to the United States were:
 - Canada, 78 percent;
 - China, 19 percent; and
 - Mexico, 80 percent.

International Overview and Physical System

A significant proportion of global freight originates from the world's leading economies. In 2008, the world's top five economies by Gross Domestic Product GDP—the United States, Japan, China, Germany, and France—together accounted for:

- 35 percent of global goods exports (\$5.6 trillion out of \$16 trillion),
- 50 percent of global GDP (\$30.1 trillion out of \$60.9 trillion), and
- 28 percent of world population (1.9 billion out of 6.8 billion people).⁵

⁵ China accounted for more than 1.3 billion people.

SOURCE: U.S. Department of Transportation, Research and Innovative Technology Administration, Bureau of Transportation Statistics, based on data from International Monetary Fund, World Economic Outlook Database, April 2009, available at www.imf.org as of Sept. 14, 2009.

- In 2008, the United States remained the world's leading economy, a position that directly reflects the level and composition of U.S. international freight transportation compared to that of the other large economies. China ranked third, a position that indicates its trade activity with the United States and freight shipments between the two countries.

Table 2. Geographic Overview of World's Top Economies: 2008

Ranked by population	National population (millions, July 2009 est.)	Population density (number of people per square kilometer)	Urban population (% of total national population, 2008)	Land area (thousands of square kilometers)
China	1,339	140	43	9,570
India	1,166	392	29	2,973
United States	307	34	82	9,162
Indonesia	240	133	52	1,812
Brazil	199	23	86	8,459
Russia	140	9	73	16,378

- The relatively larger area, lower population density, and higher urban population of the United States, in comparison to other countries, leads to relatively more freight activity. Freight must be transported greater distances as goods are shipped from production centers to consumers.

Table 3. Extent of Physical Transportation Systems in World's Top Economies: 2008

Ranked by total roadways	Roadways		Railways (km)	Waterways (km)	Pipelines (km)	Airports (number)
	Total (km)	Paved roads (km)

Indonesia	133	1.6	0.22	0.9	0.12
China	140	1.4	0.20	1.2	0.16

NOTE: In this report, intensity is defined as a ratio of the extent of the physical transportation system to the geographical area it covers and to population size. It indicates the relative concentration of the infrastructure and the size that is available for use by the population.

SOURCE: U.S. Department of Transportation, Research and Innovative Technology Administration, Bureau of Transportation Statistics, based on data from Central Intelligence Agency, *Fact Book 2009*, available at www.cia.gov as of Sept. 20, 2009.

- When road networks are viewed in relation to total land area, countries such as Japan, the United Kingdom, and France have at least twice as many kilometers of roadways per square kilometer of land area as the United States. However, if road networks are viewed in relation to population, those three countries have fewer roadway kilometers per person than the United States—the result of the lower population density and vast geographic expanse of the United States.

**Table 5. U.S. Share of World Gross Domestic Product:
1990–2008**
(Billions of current U.S. \$)

Year	World GDP	United States GDP	U.S. share of world GDP (percent)

2008	60,863	14,265	23.4

SOURCE: U.S. Department of Transportation, Research and Innovative Technology Administration, Bureau of Transportation Statistics, based on data from International Monetary Fund, World Economic Outlook Database, April 2009, available at www.imf.org, as of Sept. 14, 2009.

- Trends in global economic activities directly affect the volume of merchandise trade and worldwide movement of freight. The growing reliance on global supply chains means the effect of an economic downturn is not limited to exporting and importing nations. Other nations that provide freight and port services to transport traded goods are also affected.
- Between 2001 and 2008, the U.S. share of world GDP declined as the share of emerging and developing economies grew. Many other factors contributed to this trend, including foreign currency exchange rates, business cycles, balance of payments, and central banks policies—all of which affect the value of internationally traded goods.

Figure 3. U.S. Share of World Gross Domestic Product and Merchandise Exports: 1990–2008

SOURCES: U.S. Department of Transportation, Research and Innovative Technology Administration, Bureau of Transportation Statistics, based on data from various sources: **GDP**—International Monetary Fund, World Economic Outlook Database, April 2009. Available at www.imf.org/external/data.htm as of Sept. 14, 2009. **Trade**—International Monetary Fund, Direction of Trade Statistics. Available at www.imfststatistics.org/dot/ as of Sept. 14, 2009.

- The U.S. share of world GDP and merchandise exports increased from 1995 to 2001 during the “dot-com boom” period of U.S. economic expansion. Since 2001, the expansion of developing economies in Asia—notably China’s economy—contributed to the decline of the U.S. share of world GDP and merchandise exports.
- Top goods exports from the United States include civilian aircraft and parts, motor vehicles and parts, electrical equipment, electronics, and medical equipment (USDOT CB FTD 2009).

Available at www.imfstatistics.org as of Sept. 14, 2009.

- In 2008, the United States was the world's third-ranked exporting nation, behind China and Germany. U.S. goods exports accounted for 8 percent of the value of worldwide exports.
- Among the world's top exporting nations, Canada and Mexico ranked 10th and 15th, respectively.
- The majority of exports from Canada and Mexico continue to be bound for the United States. Most enter by surface modes of transportation.
- The United States received nearly one-fifth (19 percent) of the exports from China. The top exports from China to the United States include finished goods such as computer equipment, electronics, toys, apparel, furniture, and other household goods.

NOTE: Hong Kong is a special administrative region of China, but is separate from China in U.S. Foreign Trade Statistics.

SOURCES: U.S. Department of Transportation, Research and Innovative Technology Administration, Bureau of Transportation Statistics, based on data from various sources. **United States**—U.S. Department of Commerce, U.S. Census Bureau, Foreign Trade Division, available at www.census.gov as of May 12, 2009. **World**—International Monetary Fund, Direction of Trade Statistics, available at www.imfstatistics.org as of Sept. 14, 2009.

- The United States is the world's largest importer of goods. Crude oil, petroleum products, passenger motor vehicles, electrical machinery, and electronics are among the top imports by value (USDOT CB FTD 2009).
- Canada, Mexico, and Brazil's imports from the United States account for a large proportion of their overall imports.
- Over half of Canada's imports are from the United States. Canada's top imports from the United States include passenger cars, trucks, buses, vehicle parts, and civilian aircraft.
- Nearly half of Mexico's imports are from the United States. The top imports from the United States are motor vehicles and parts, electronic equipment and parts, electrical apparatus, and petroleum products.

- The United States accounted for about 15 percent of imports into Brazil, an important emerging economy. Top imports into Brazil from the United States include civilian aircraft and parts, computer equipment, and telecommunications equipment.
- In 2008, China imported less from the United States (\$81 billion) than it exported to the United States (\$273 billion). Its imports from the United States accounted for 7 percent of the country's total imports, and its exports to the United States accounted for 19 percent of its total exports.

Figure 4. U.S. Share of World Merchandise Trade: 1990–2008

SOURCES: U.S. Department of Transportation, Research and Innovative Technology Administration, Bureau of Transportation Statistics, based on data from various sources. **United States**—U.S. Department of Commerce, U.S. Census Bureau, Foreign Trade Division, available at www.census.gov/foreign-trade/index.html as of May 12, 2009. **World**—International Monetary Fund, Direction of Trade Statistics. Available at www.imfstatistics.org/dot/ as of Sept. 14, 2009.

- From 1990 to 2008, the U.S. share of the world's total imports was larger than its share of exports. During this period, the U.S. share of total exports fell faster than its share of the world's total imports (IMF 2009).

Worldwide Oceanborne and Air Freight

Stock photo

Businesses rely on all freight modes to transport international merchandise trade. Often, goods are moved by a multimodal combination of airplanes, maritime vessels, trains, and trucks.

Figure 5. Worldwide Oceanborne Cargo

Figure 6. Worldwide Air Cargo

NOTE: Although figures 5 and 6 are not to the same scale, they both show nearly a doubling of cargo, by weight, over identical time spans.

SOURCES: U.S. Department of Transportation, Research and Innovative Technology Administration, Bureau of Transportation Statistics, based on data from various sources. **Oceanborne cargo**—United Nations Conference on Trade and Development, Review of Maritime Transport, various issues, available at www.unctad.org/rmt as of Oct. 3, 2009. **Air cargo**—International Civil Aviation Organization (ICAO), special tabulations, Sept. 28, 2009.

- In 2007, the most recent year for which data are available, the volume of worldwide international oceanborne cargo reached more than 8 billion tons. During the past decade, the annual average growth rate was about 3 percent.
- Worldwide international air cargo reached 28 million tons in 2007, growing at an annual average rate of 5 percent over the past decade. This growth trend reflects continuing globalization of economic activities and increasing adoption of inventory management strategies.
- By weight, the overwhelming majority of global overseas merchandise trade is carried by ocean vessel rather than airplane (excluding land modes of transportation). While generally ocean vessels transport low value-per-ton commodities (e.g., crude oil, grains, and coal), container vessels transport high value-per-ton manufactured goods of all kinds, such as automobiles, appliances, computer equipment, and apparel.

Figure 7. Worldwide Overseas Oceanborne and Air Cargo by Weight: 1995–2007

SOURCES: U.S. Department of Transportation, Research and Innovative Technology Administration, Bureau of Transportation Statistics, based on data from various sources. **Oceanborne cargo**—United Nations Conference on Trade and Development, Review of Maritime Transport, various issues, available at www.unctad.org/rmt as of Oct. 3, 2009. **Air cargo**—International Civil Aviation Organization (ICAO), special tabulations, Sept. 28, 2009.

- By weight, air carriers carry less global merchandise trade than ocean vessels. Air carriers transport high value-per-ton commodities. During the past decade, however, the tonnage of air cargo transported globally grew at a faster rate than total oceanborne cargo.
- Air cargo tonnage grew as demand for international express traffic increased and shippers sought more time-definite deliveries. While ocean carriers provide lower transportation costs, air carriers provide faster delivery times.
- Containerized cargo, a segment of the maritime industry that, like air cargo, includes high value-per-ton goods, grew faster than air cargo and total oceanborne cargo during this period.

Table 8. Value and Weight of Worldwide and U.S. Oceanborne Export Freight: 1995–2007

Year	World exports		U.S. exports	
	Value (billions U.S. \$)	Weight (millions of short tons)	Value (billions U.S. \$)	Weight (millions of short tons)

2004	4,551	6,893	234	416
2005	5,290	7,122	263	402
2006	6,301	7,761	308	434
2007	7,723	8,032	375	467

SOURCES: U.S. Department of Transportation, Research and Innovative Technology Administration, Bureau of Transportation Statistics, based on data from various sources.

World: Value—IHS Global Insight World Trade Service, special tabulations from June 2009 Forecast Series, as of Sept. 29, 2009. **Weight**—United Nations Conference on Trade and Development, Review of Maritime Transport, various issues, available at www.unctad.org as of Oct. 3, 2009.

United States: Value—U.S. Department of Transportation, Maritime Administration, available at www.marad.gov as of Oct. 2, 2009. **Weight**—U.S. Army Corps of Engineers, Waterborne Commerce of the United States 2007, Table 1-6, available at www.iwr.usace.army.mil as of Oct. 2, 2009.

- Between 1995 and 2007, world oceanborne export freight, as measured by weight, nearly doubled to 8 billion short tons. By comparison, the total weight of U.S. oceanborne exports remained steady.
- The weight, value, and physical characteristics of oceanborne cargo determine the type of vessels used for particular shipments (tanker, container, or bulk) and the seaports where they call. In 2008, Houston was the leading U.S. port by weight and Los Angeles was the top container port (USDOT RITA BTS 2009b).

Figure 8. Worldwide and U.S. Maritime Industry Ton-Miles: 1995–2007

SOURCES: U.S. Department of Transportation, Research and Innovative Technology Administration, Bureau of Transportation Statistics, based on data from various sources. **World**—United Nations Conference on Trade and Development, Review of Maritime Transport, various issues, available at www.unctad.org/rmt as of Oct. 3, 2009. **United States**—U.S. Army Corps of Engineers, Waterborne Commerce of the United States 2007, Table 1-6, available at www.iwr.usace.army.mil/ndc/wcsc/wcsc.htm as of Oct. 2, 2009.

- During the past decade, the demand for maritime freight services, as measured by ton-miles, grew faster globally than for U.S. international freight. From 1995 to 2007, global maritime ton-miles grew at an average annual rate of 4 percent. Ton-miles grew less than 1 percent for the United States over the same period.
- Global ton-miles grew faster as China and other countries increased oil imports from places other than the Middle East (e.g., Angola) and increased purchases of dry bulk cargo (e.g., iron ore) from South America (UNCTAD 2008).

Figure 9. U.S. Air Carriers' Share of Worldwide International Tons and Revenue Ton-Kilometers: 1995-2008

NOTE: The U.S. data were converted from short ton-miles to ton-kilometers. To convert short ton-miles to metric ton-kilometers, first multiply by 1.61 (for kilometers) and then divide by 1.1 (for metric tons).

SOURCES: U.S. Department of Transportation, Research and Innovative Technology Administration, Bureau of Transportation Statistics, based on data from various sources. **World**—International Civil Aviation Organization (ICAO), special tabulations, Sept. 28, 2009. **United States**—USDOT, RITA, BTS, Office of Airline Information, TranStats—tonnage: T100-Segment data (U.S. carriers only); ton-kilometers: T2-U.S. Air Carrier Traffic and Capacity Statistics, available at www.bts.gov as of Sept. 29, 2009.

- In 2008, U.S. air carriers carried about 4.4 million tons of international air cargo, accounting for 18 percent of the 25 million tons transported globally in international service. U.S. air carriers' international cargo traffic generated 33 billion revenue ton-kilometers, accounting for 25 percent of about 131 billion revenue ton-kilometers of global international air cargo traffic.
- Since 2005, the U.S. share of world air cargo tonnage and ton-kilometers has declined as the annual growth rates of Asia's air cargo markets increased.

Worldwide Ports

E-Ternational

Seaports and airports are vital components of the freight system. They enable global trade and facilitate international economic activities.

In 2007, ports worldwide handled more than 8 billion tons of oceanborne exports and more than 25 million tons of international air cargo. This freight included raw materials, manufactured products, and everyday items found at businesses and homes, such as laptop computers, precision medical instruments, flat-panel televisions, bicycles, and furniture.

Table 9. Leading World Maritime Ports by Cargo Weight: 2007
(Thousands of metric tons)

Rank	Port name	Country	Tons
1	Shanghai	China	561,446
2	Singapore	Singapore	483,616
3	Ningbo-Zhoushan	China	471,630
4	Rotterdam	Netherlands	401,181
5	Guangzhou	China	341,363
6	Tianjin	China	309,465
7	Qingdao	China	265,020
8	Qinhuangdao	China	245,964
9	Hong Kong	China	245,433
10	Busan	South Korea	243,564
11	Dalian	China	222,859
12	Nagoya	Japan	215,602
13	South Louisiana	United States	207,785
14	Shenzhen	China	199,190
15	Kwangyang	South Korea	198,190
16	Houston	United States	196,014
17	Antwerp	Belgium	182,897
18	Chiba	Japan	169,202
19	Ulsan	South Korea	168,652
20	Kaohsiung	Taiwan	149,225
21	New York/New Jersey	United States	142,614
22	Yokohama	Japan	141,758
23	Hamburg	Germany	140,923
24	Incheon	South Korea	138,139
25	Port Kelang	Malaysia	135,514

NOTE: The original source of the data in this table, the American Association of Port Authorities, notes that the metric tons used for the rankings are estimates from various sources, including the individual seaports, and are based on cargo weights, volumes, and units. As such, the figures cannot be converted into a single standardized measure such as TEUs. Because of this, the estimates are also not directly comparable across all seaports.

SOURCE: U.S. Department of Transportation, Research and Innovative Technology Administration, Bureau of Transportation Statistics, based on data from American Association of Port Authorities. Port Industry Statistics. World Port Rankings: 2007, available at www.aapa-ports.org as of Sept. 30, 2009.

- By weight, 7 of the world's top 10 seaports in 2007 were in China. Three U.S. ports—South Louisiana, Houston, and New York/New Jersey—ranked among the top 25.

Table 10. Top 20 World Container Ports by TEUs Handled: 2007 and 2008
(Thousands of loaded and unloaded TEUs)

Rank in 2008	Port name	Country	2007	2008	Percent change, 2007–2008
1	Singapore	Singapore	27,932	29,918	7.1
2	Shanghai	China	26,150	27,980	7.0
3	Hong Kong	China	23,881	24,248	1.5
4	Shenzhen	China	21,099	21,414	1.5
5	Busan	South Korea	13,270	13,425	1.2
6	Dubai	United Arab Emirates	10,653	11,828	11.0
7	Ningbo	China	9,360	11,226	19.9
8	Guangzhou	China	9,200	11,001	19.6
9	Rotterdam	Netherlands	10,791	10,800	0.1
10	Qingdao	China	9,462	10,320	9.1
11	Hamburg	Germany	9,900	9,700	-2.0
12	Kaohsiung	Taiwan	10,257	9,677	-5.7
13	Antwerp	Belgium	8,177	8,664	6.0
14	Tianjin	China	7,103	8,500	19.7
15	Port Klang	Malaysia	7,120	7,970	11.9
16	Los Angeles	United States	8,355	7,850	-6.0
17	Long Beach	United States	7,312	6,488	-11.3
18	Tanjung Pelepas	Malaysia	5,500	5,600	1.8
19	Bremen/Bremerhaven	Germany	4,892	5,501	12.4
20	New York/New Jersey	United States	5,400	5,265	-2.5

KEY: TEUs = twenty-foot equivalent units. One 20-foot container equals one TEU, and one 40-foot container equals two TEUs.

SOURCES: 2000 and 2007—U.S. Department of Transportation, Research and Innovative Technology Administration, Bureau of Transportation Statistics, based on Maritime Administration, 2008—Containerisation International Online, www.ci-online.co.uk as of Mar. 17, 2009.

- In 2008, three U.S. ports—Los Angeles, Long Beach, and New York/New Jersey—ranked among the top 20 world container ports. Six of the top 10 were in China.

NOTE: Total tons handled—loaded and unloaded freight and mail in metric tons.

SOURCE: U.S. Department of Transportation, Research and Innovative Technology Administration, Bureau of Transportation Statistics, based on data from Airports Council International, available at www.aci.aero as of Sept. 29, 2009.

- In 2008, most of the world's leading airports for handling international cargo experienced declines in freight traffic compared to the previous year.
- All 5 U.S. airports ranked among the world's top 25 air freight airports —Miami, Ted Stevens Anchorage, John F. Kennedy, O'Hare, and Los Angeles—shipped less freight in 2008 than in 2007.

Worldwide Freight Carriers

Nina Chantasm

Shipping lines, airlines, all-cargo air couriers, trucking firms, and railroads provide services that link shippers, ports, and consignees. Managing product supply chains and transporting goods globally involves considerable interaction across the carrier industry. During the past decade, businesses expanded sourcing of raw materials and finished goods from multiple locations around the world, and the air and ocean freight carrier industries that provide overseas services adapted their freight operations in response.

Globally, the leading all-cargo air carriers include FedEx, UPS, DHL, and TNT. Leading airlines that provide cargo services include Lufthansa, Korean Air Lines, Singapore Airlines, British Airways, and Air France (IATA 2009b). The air-freight carrier industry continued its heavy reliance on hub-and-spoke operations⁶ that allow carriers to connect several origins with multiple destinations without having all the points connected directly.

⁶ Hub-and-spoke operations describe a route structure in which airlines arrange flights like a wheel with all traffic moving along spokes to and from a central location—the hub. In the 1980s, most airlines changed their operations from a linear point-to-point network to a hub-and-spoke network (USDOT RITA BTS 1996).

Expanded use of hub networks allowed the airlines to control fleet size and capacity while serving many markets. It also allowed them to cut operating costs and offer improved integrated cargo delivery services. Airlines that carry commercial freight in aircraft cargo holds during passenger flights continued to expand their cargo services beyond their immediate networks by forming alliances. Examples of industry alliances among the leading airlines include United-Lufthansa, Northwest-KLM, Delta-China Airlines, and American Airlines-Mexicana Airlines.

Worldwide, the leading ocean container carriers include APM-Maersk Line, Mediterranean Shipping Company, CMA CGM, Evergreen Line, and American President Lines (APL) (AXS-Alphaliner 2009b). During the past decade, the ocean-shipping industry continued consolidations begun in the 1990s. Carriers engaged in vessel-sharing arrangements⁷ that allowed them to serve multiple ports by connecting to larger hub seaports. These hub ports provide feeder vessel services to smaller ports and often use intermodal rail and truck carriers for deliveries to final destinations. Some of the major inter-carrier alliances, mergers, and acquisitions include Maersk and Sea-Land, Neptune Orient Line and APL, and Maersk and P&O Nedlloyd.

In April 2008, the world's three largest container lines—Danish carrier Maersk Line, Swiss carrier Mediterranean Shipping Company, and French-based CMA–CGM—started a significant vessel-sharing agreement in the Asia-North America trade lane that enables them to replace their own individual services with joint services (Maersk Line 2008). In September 2009, Maersk Line and CMA CGM merged services between the east coast of South America, Central America, and the Caribbean (Maersk Line 2009).

**Table 13. Leading World Maritime Container Carriers by Fleet Size: September 2009
(Ranked by TEUs)**

Rank	Carrier	Company	Country of owner	Fleet size (TEUs in thousands)	Ships

U.S. Trends

USDOT, RITA, BTS

In 2008, U.S. freight gateways handled more than \$3.4 trillion (in current dollars) of international merchandise trade. From 2007 to 2008, merchandise exports rose 12 percent, and imports rose 7 percent. Since 1990, the leading U.S. freight gateways have handled increasing volumes of freight as the movement of traded goods to and from the United States has expanded.

From 1990 to 2008, the value of U.S. international merchandise trade grew from \$889 billion to \$3.4 trillion, increasing at an average annual rate of 8 percent. In inflation-adjusted terms (using chained 2000 dollars), this trade grew about 7 percent per year, from \$837 billion to more than \$2.6 trillion. During this period, the growth in merchandise trade spurred the development of marine, air-cargo, and border-crossing facilities to connect domestic U.S. origins and destinations to markets abroad.

MODAL VIEW

Figure 10. Modal Shares of U.S. Merchandise Trade Handled by Land, Water, and Air Gateways by Value and Weight: 2007¹

¹ BTS estimated the export weight for truck, rail, pipeline, and other and unknown based on value-to-weight ratios from the import data. This estimation procedure was used because U.S. exporters are not currently required to report the export weight for land modes. Weight for water and air exports and imports are from U.S. Department of Commerce, U.S. Census Bureau.

² Includes truck, rail, and pipeline modes.

³ Includes purchased vehicles such as aircraft or boats moving from manufacturer to customer where the vehicle itself is the shipment, pedestrians carrying freight, and miscellaneous.

- Nearly all shipments require the use of more than one mode of transportation to reach their final destinations. For example, a shipment of imported goods arriving at a maritime port is transferred to rail or truck to continue its journey. Railroads tend to carry commodities long distances at low prices, while trucks often carry commodities shorter distances and more quickly.
- Waterborne vessels account for more U.S. international trade, both in terms of tonnage and value, than any other mode—78 percent of the weight and 45 percent of the value of U.S. merchandise trade in 2007. Water transportation is less dominant in terms of value because high value-per-ton commodities often move by air and truck, particularly in U.S. trade with Canada and Mexico.
- Intermodal rail traffic—the transport of containers or truck trailers by rail—has significantly increased during the past two decades.

FREIGHT CARRIER AND PORT SERVICES

Figure 11. U.S. International Freight and Port Services Trade: 1990–2008

NOTE: Data cover total payments and receipts. Payments consist of money paid by domestic consumers to foreign carriers or service providers. Receipts consist of money received by domestic carriers or service providers from foreign sources.

SOURCE: U.S. Department of Transportation, Research and Innovative Technology Administration, Bureau of Transportation Statistics, based on data from U.S. Department of Commerce, Bureau of Economic Analysis, U.S. International Transactions Accounts Data, available at www.bea.gov/international/bp_web/simple.cfm?anon=104324&table_id=22&area_id=3 as of Sept. 10, 2009.

- Freight carriers transport international cargo between the United States and its trading partners around the world. In addition to trade in merchandise, the United States buys (imports) and sells (exports) freight services via the various transportation modes. The freight and port services sector includes several industries, including carriers, ports, terminal operators, and third-party logistics providers, such as freight forwarders and consolidators.
- In 2008, U.S. trade in freight and port services was \$131 billion. Receipts for exports were \$59 billion, and payments for imports were \$72 billion. Of the \$131 billion, 52 percent (\$68 billion) was for freight services and the remainder was for port services.

Table 16. U.S. International Freight and Port Services Trade: 1990–2008
(Billions of current \$)

Year	Total		Freight services		Port services	
	Freight services	Port services	Receipts (exports)	Payments (imports)	Receipts (exports)	Payments (imports)
1990	23.4	23.6	8.4	15.0	13.7	9.9

2007	65.4	53.2	19.8	45.6	31.7	21.5
2008	67.7	63.4	22.4	45.2	36.5	26.9

NOTE: Payments consist of money paid by domestic consumers to foreign carriers or service providers. Receipts consist of money received by domestic carriers or service providers from foreign sources.

SOURCE: U.S. Department of Transportation, Research and Innovative Technology Administration, Bureau of Transportation Statistics, based on data from U.S. Department of Commerce, Bureau of Economic Analysis, U.S. International Transactions Accounts Data, available at www.bea.gov as of Sept. 10, 2009.

- In 2008, U.S. receipts for freight transportation services totaled \$22 billion, double the amount in 1998. Payments for freight services were \$45 billion, more than twice the amount in 1998.
- From 1998 to 2008, receipts and payments for port services more than doubled, to \$37 billion and \$27 billion respectively.

BOX A

U.S. THIRD-PARTY LOGISTICS PROVIDERS INDUSTRY

An important segment of the movement of U.S. international freight is the third-party logistics providers industry. The Council of Supply Chain Management Professionals defines third-party logistics (3PL) as the “outsourcing all or much of a company’s logistics operations to a specialized company.” Such outsourcing, allows shippers to focus on their core business activities while entrusting transportation, warehousing, customs-related, and other value-added activities to specialists able provide such services. In the United States, the use of 3PL providers by both large and small businesses has increased over time. Figure 12 shows the gross revenues of the U.S. 3PL industry from 1996 to 2008.

Figure 12. Gross Revenues of the U.S. Third-Party Logistics Providers Industry: 1996–2008

SOURCE: U.S. Department of Transportation, Research and Innovative Technology Administration, Bureau of Transportation Statistics, based on data from Armstrong & Associates, Inc. 2009. U.S. and Global Third-Party Logistics Market Analysis. Available at http://3plogistics.com/PR_3PL_Financial-2009.htm as of Nov. 1, 2009.

Classification of 3PLs. The third-party logistics providers (3PL) industry could be categorized into asset-based and nonasset-based companies. Asset-based 3PLs own their own trucks and distribution centers. They are more suitable for large corporations requiring long-term contracts and value-added international transportation management services (Cain 2007). Asset-based 3PLs often work in conjunction with freight forwarders. Nonasset-based 3PLs do not own the vehicles or equipment used in providing their services. These firms are the majority of 3PLs. They contract with trucking companies, other carriers, and distribution centers for whatever they need to fulfill their services. This provides them more flexibility than the asset-based firms and they are able to offer expedited and customizable supply chain solutions. Nonasset-based

operators include air freight forwarders, truck freight brokers, intermodal marketing companies, and distribution entities (Cain 2007).

Outsourcing to 3PLs. Over the past decade, many companies have turned to outsourcing services not core to their line of business (Capgemini et. Al. 2009). Transportation and warehousing are the two most frequently outsourced activities. Table 17 summarizes the most common outsourced operations. Table 18 shows the leading global 3PL providers in 2008.

Table 17. Outsourced Logistics Services: 2008
(Percent of outsourced operations)

Logistics activity	All regions	North America	Europe	Asia Pacific	Latin America
Domestic transportation	86	75	92	95	80

SOURCE: U.S. Department of Transportation, Research and Innovative Technology Administration, Bureau of Transportation Statistics, based on Armstrong & Associates, Inc. A&A's Top 50 Global Third-Party Logistics Provider (3PL) List, available at 3plogistics.com as of Nov. 1, 2009.

Summary. Third-party logistics (3PL) providers are an important class of logistics intermediaries operating in the freight industry. These firms receive more than \$100 billion in revenues and make more than \$50 billion in payments to transportation carriers. While 3PLs are important to the freight industry, there is little information about the commodities they help transport and the value and tonnage of those commodities.

Summary

There are dynamic industry-wide changes that continue to influence and shape the global freight industry as worldwide international trade is transformed by the global economy. The principal forces that are likely to affect future international merchandise trade and freight movements include the following:

- changes in U.S. reliance on imported consumer products,
- China's expanded role in the world economy and global trade,
- fluctuations in fuel prices and transportation costs,
- environmental concerns, and
- a rise in Internet shopping and on-demand deliveries.

These global forces and the pace of U.S. reliance on imported consumer products may affect the movement of freight from, to, and within the United States. Increased freight movements resulting from future resumption of growth in worldwide merchandise trade could affect U.S. freight gateways and the relative dominance of particular seaports, airports, and land border crossings.

PRINCIPAL FORCES OF CHANGE

Changes in U.S. reliance on imported consumer products. Like other leading world economies, the United States has seen its domestic economy shift from manufacturing and agriculture to an emphasis on service and information industries (USDOT FHWA 2007a). As the output of the U.S. information and service sectors expanded, American demand for consumer goods continued to increase steadily over the last two decades (Moran and McCully 2001). At the same time, U.S. businesses outsourced more parts and finished products from trading partners around the world. Together, those trends led the United States to rely more significantly on imports of consumer goods to meet growing domestic demand for manufactured products. A resumption of growth in U.S. demand for foreign consumer goods would spur an increase in international freight handled by U.S. gateways.

China's expanded role in the world economy and global trade. As the world's largest developing economy, China has emerged as a significant force in global trade. Since China opened its markets, its economic impact in the world has expanded rapidly. During the past two decades, China increased its industrial output and became the world's top manufacturer (CRS 2007). In 2008, China was the United States' second leading trading partner. China was also a top trading partner for the world's other developed economies, including Japan and the European Union. Continued growth in China's economic position, coupled with its continuing demand for raw materials and parts from around the world, will significantly fuel growth in global merchandise trade and freight movements.

Fluctuations in fuel prices and transportation costs. In 2007 and 2008, concerns about increased fuel prices and transportation costs emerged as oil price fluctuations seriously impacted freight carriers. When fuel prices rise, transportation costs become more important relative to the cost of inventory or shipping (Hummels 2009). If wide fluctuations in fuel prices continue in coming years, they could have the effect of reconfiguring global production, distribution, and freight transportation services. Significant fluctuations in world fuel prices could seriously affect the financial performance of freight carriers engaged in international trade, and could also change industry alliances and recent patterns of carrier cooperation.

Environmental concerns. While freight transportation is essential to continued economic growth, like other industrial activities it can have an unintended and negative impact on environmental quality (USDOT RITA BTS 2008). Some of the most prominent environmental concerns surrounding freight transportation include the following:

- *Climate change.* Transportation is the second-largest source of greenhouse gases, accounting for a significant proportion of the world's carbon dioxide emissions.
- *Pollution, water, and air quality.* Pollutants produced through the operation of the freight trucks—such as carbon monoxide, ozone, nitrogen oxide, and sulfur dioxide—contribute to climate change and harm human health. The use of larger maritime vessels increases the need for harbor dredging and increases the amount of ballast water produced, a factor that can help introduce nonindigenous aquatic species into waterways.
- *Land-use compatibility around maritime ports.* Increased port traffic exacerbates congestion on landside transportation systems, increasing vehicle delays and emissions.

Global and national actions aimed at mitigating these environmental impacts could potentially affect the worldwide freight industry in terms of future technology adoption, performance, and growth.

Rise in Internet shopping and on-demand deliveries. The continued popularity and acceptance of Internet shopping, coupled with increased adoption of just-in-time inventory management by shippers globally, has had an impact on how freight moves. Internet shopping requires carriers to deliver goods to end users rather than to intermediaries, resulting in overall growth in direct shipments to customers (USDOT FHWA 2007b). Together, these trends have increased the number of shipments, particularly small shipments, that carriers handle, and expanded the number of links in the freight supply chain that are needed to deliver goods to their final destination.

SUMMARY AND CONCLUSION

Globally, more than 8 billion tons of freight moved in international maritime and air transportation in 2008. A vast number of vessels, aircraft, and vehicles operated by several freight carriers moved these goods around the world. The major highlights of this report include the following:

- The majority of international freight transported worldwide comes from a few countries. In 2008, more than three-quarters of exported freight were from only 25 countries.

- From mid-2008 to mid-2009, as global economic activities slowed, goods transported worldwide by ocean carriers and airlines fell.
- Since 2001, U.S. shares of world GDP and exports have fallen as the share of developing Asian countries, particularly China, increased.
- Ocean carriers continue to transport the majority of internationally traded goods. During the past decade, worldwide containerized cargo grew faster than air cargo.
- In 2008, three U.S. seaports—South Louisiana, Houston, and New York/New Jersey—ranked 13th, 16th, and 21st, respectively among the world's top ports.
- Among the world's top container ports, Los Angeles, Long Beach, and New York/New Jersey ranked 16th, 17, and 20th, respectively.
- Among the world's top airports, Miami, Ted Stevens Anchorage, and John F. Kennedy ranked 10th, 12th, and 15th, respectively.

Changes in the global economic situation as well as trade between nations will continue to affect the choices of transportation modes used in transporting traded goods around the world and in the United States. Resumption of growth in worldwide merchandise trade is likely to create more demand for intermodal freight services. Continued integration of global economic activities and resumption of growth in oceanborne and air cargo would increase demand for freight transportation services.

Global economic activities will continue to shape where and how goods are produced and distributed. Expanded trade among countries will ultimately affect the movement of freight internationally as well as into and out of the United States. Fuel costs, changes in logistics supply chains, out-sourcing, just-in-time inventory management systems, and online shopping could impact the demand for freight transportation.

Clean Cities Alternative Fuel Price Report

October 2013

U. S. Department of Energy

WELCOME!

Welcome to the October 2013 issue of the Clean Cities Alternative Fuel Price Report, a quarterly report designed to keep Clean Cities coalitions and other interested parties up to date on the prices of alternative and conventional fuels in the United States. This issue summarizes prices that were collected between October 4, 2013 and October 18, 2013 from Clean Cities Coordinators, fuel providers, and other Clean Cities stakeholders.

METHODOLOGY

In order to collect price information for both alternative and conventional fuels from areas across the country, Clean Cities coordinators, fuel providers, and other key stakeholders were requested to provide prices for fuels in their areas on a voluntary basis. Prices were collected on all major alternative fuels currently in widespread use (natural gas, propane, biodiesel, and ethanol), as well as prices for conventional fuels at stations that also sell alternative fuels (or stations nearby). Prices were collected from public and private refueling stations throughout the country between October 4, 2013 and October 18, 2013. Prices were then averaged to determine regional price trends by fuel and variability in fuel price within and among regions.¹ Consistent with the fuel price reporting format the U.S. Energy Information Administration (EIA) uses, prices in this report are grouped by the Petroleum Administration for Defense Districts (PADD); the districts are illustrated in the map to the right.

This report's prices represent retail, at-the-pump sales prices for each fuel, including federal and state motor fuel taxes. In some cases, prices were collected from government or utility refueling facilities and these taxes were not included in the prices reported to Clean Cities. In these instances, although these users are not required to pay these taxes, the appropriate federal and state taxes were added to the reported prices to provide a more representative basis for comparison. In some cases, states may charge a flat annual fee for state motor fuel taxes, especially for gaseous fuels like compressed natural gas (CNG) and liquefied petroleum gas (LPG or propane). These flat fees are not considered in the prices reported in these pages.

¹ Fuel price averages for this report are determined by simply averaging the individual data points received. A comparison of average fuel prices for private and for public stations by region can be found on pages 13-14.

SUMMARY OF CURRENT REPORT INFORMATION

Table 1 shows overall nationwide average prices for conventional and alternative fuels.² As this table illustrates, alternative fuel prices relative to conventional fuels vary, with some (B20, B99-B100) higher and some (CNG, E85 and propane) lower. On an energy-equivalent basis, CNG is about \$1.36 less than gasoline. On a per-gallon basis, E85 is about 41 cents less than gasoline, and propane is about 49 cents less than gasoline. B20 prices are higher than regular diesel by about 11 cents, while B99/B100 blends have a cost of about 27 cents per gallon more than regular diesel.³

Table 1. Overall Average Fuel Prices

	Nationwide Average Price for Fuel This Report	Nationwide Average Price for Fuel Last Report	Change in Price This Report vs. Last Report	Units of Measurement
Gasoline (Regular)	\$3.45	\$3.65	(\$0.20)	per gallon
Diesel	\$3.91	\$3.91	\$0.00	per gallon
CNG	\$2.09	\$2.14	(\$0.05)	per GGE
Ethanol (E85)	\$3.04	\$3.23	(\$0.19)	per gallon
Propane	\$2.96	\$2.73	\$0.23	per gallon
Biodiesel (B20)	\$4.02	\$3.89	\$0.13	per gallon
Biodiesel (B99-B100)	\$4.18	\$4.19	(\$0.01)	per gallon

Relative to the last report from July 2013, the average prices for most of the liquid fuels have decreased by as much as 20 cents, while B20 increased by 13 cents. The gaseous fuel prices experienced a decrease of 5 cents for CNG and an increase of 23 cents for propane. It should be noted that the price changes occur as a result of a number of factors, including an actual change in price, a slightly differing sample of prices (both location and quantity), and seasonal variations of demand.

Prices in this report were collected and are reported in the units in which they are typically sold (dollars per gallon or dollars per gasoline gallon equivalent). Because these fuels have differing energy contents per gallon, the price paid per unit of energy content can differ somewhat from the price paid per gallon. Table 2 shows the fuel prices from Table 1 for the current reporting period normalized to a price per gasoline gallon equivalent (GGE), per diesel gallon equivalent (DGE), or per million British thermal units (BTUs) of energy. This calculation uses the nominal lower heating values in BTUs per gallon of fuel from the Oak Ridge National Laboratory's Transportation Energy Data Book.⁴ Prices for the alternative fuels in terms of price per gallon equivalent are generally higher than their price per gallon because of their lower energy content per gallon.⁵ However, consumer interest in alternative fuels generally increases when the alternative fuel price is less than the conventional fuel price and as the price differential per gallon increases, even if that differential does not directly translate to savings on an energy-equivalent basis.

Table 2. October 2013 Overall Average Fuel Prices on Energy-Equivalent Basis

	Nationwide Average Price in Gasoline Gallon Equivalents	Nationwide Average Price in Diesel Gallon Equivalents	Nationwide Average Price in Dollars per Million Btu
Gasoline	\$3.45	\$3.84	\$29.85
Diesel	\$3.51	\$3.91	\$30.39
CNG	\$2.09	\$2.33	\$18.07
Ethanol (E85)	\$4.30	\$4.80	\$37.29
Propane	\$4.09	\$4.56	\$35.46
Biodiesel (B20)	\$3.67	\$4.09	\$31.79
Biodiesel (B99-B100)	\$4.12	\$4.59	\$35.70

² A very small sample (5 points) of hydrogen information was received: One of the five locations for which data was received reported hydrogen at zero cost for vehicle use, with an average price for the four other hydrogen stations of \$2.77 per gasoline gallon equivalent.

³ ASTM specifications now include blends of up to 5% biodiesel as regular diesel fuel; therefore the separate listing for B2/B5 was discontinued as of October 2009.

⁴ A listing of the conversion factors used appears as an appendix at the end of this report.

⁵ For ethanol flexible-fuel vehicles (FFVs), the actual difference in fuel used per mile is somewhat less than would be calculated simply on the difference in energy content of the fuels, as some sources have noted that some FFVs can achieve better energy efficiency (miles per unit of energy) on E85 than on gasoline. This effect is not currently included in these calculations as the magnitude of the effect varies by specific FFV model.

GASOLINE AND DIESEL PRICES

Table 3 shows average prices for gasoline and diesel as collected by Clean Cities coordinators and other stakeholders (supplemented where necessary with other EIA reference sources for conventional fuels). These prices were collected from refueling stations selling both conventional fuels and alternative fuels, and from conventional refueling stations near alternative fuel stations. There were 516 price points collected for gasoline and 350 for diesel. The average price for gasoline ranged from a low of \$3.11 per gallon in the Gulf Coast region to a high of \$3.78 per gallon in the West Coast region. Diesel prices ranged from \$3.78 per gallon in the Central Atlantic and Gulf Coast regions to \$4.11 per gallon in the West Coast region. Because prices for conventional fuels were collected from stations and regions providing alternative fuel price information, data collection was not uniform across the regions of the country. However, the information is representative of refueling stations selling both alternative fuels and conventional fuels.

Table 4 shows average prices as provided by EIA on the petroleum information section of its website.⁶ These prices are averages of prices from a selection of 900 gasoline and 350 diesel retail fuel stations across the country. Note that EIA's average nationwide prices match relatively closely with the average prices reported by Clean Cities stakeholders. Prices differed by 10 cents or less for gasoline and 6 cents or less for diesel in each region on a per gallon basis, with the exceptions of New England, where EIA average prices for gasoline differed by 23 cents, and the Central Atlantic, where EIA average prices for diesel differed by 18 cents from the average prices reported by Clean Cities stakeholders. Comparisons in this document between conventional and alternative fuel prices will be made using prices collected from Clean Cities sources wherever possible, as these prices are most representative of stations selling both conventional and alternative fuels.

Table 3. Average Gasoline and Diesel Prices by Region from Clean Cities Sources

	Regular Gasoline Information Reported by Clean Cities (\$/gal)		Diesel Information Reported by Clean Cities (\$/gal)	
	Average Price	Number of Data Points	Average Price	Number of Data Points
New England	\$3.76	27	\$4.09	33
Central Atlantic	\$3.41	54	\$3.78	47
Lower Atlantic	\$3.34	62	\$3.83	42
Midwest	\$3.32	138	\$3.81	87
Gulf Coast	\$3.11	40	\$3.78	18
Rocky Mountain	\$3.42	94	\$3.89	45
West Coast	\$3.78	101	\$4.11	78
NATIONAL AVERAGE	\$3.45	516	\$3.91	350

Table 4. EIA Gasoline and Diesel Price Averages

	Gasoline Average Price from EIA, Week of 10/14/13	Diesel Average Price from EIA, Week 10/14/13
New England	\$3.53	\$4.03
Central Atlantic	\$3.40	\$3.96
Lower Atlantic	\$3.26	\$3.84
Midwest	\$3.30	\$3.85
Gulf Coast	\$3.11	\$3.80
Rocky Mountain	\$3.46	\$3.89
West Coast	\$3.68	\$4.05
NATIONAL AVERAGE	\$3.35	\$3.89

⁶ <http://www.eia.doe.gov/petroleum/>

COMPRESSED NATURAL GAS (RELATIVE TO GASOLINE)

Table 5 shows average prices for compressed natural gas (CNG) for vehicle use, grouped by region, as well as regular gasoline prices, as provided by Clean Cities representatives. These prices were collected from across the country from Clean Cities coordinators, fuel providers, and other stakeholders on a voluntary basis.

As Table 5 illustrates, CNG has a lower average price than gasoline for all regions of the country, with the largest difference (\$1.60 per GGE) being in the Rocky Mountain region. On average, CNG costs about \$1.36 less than gasoline on a per gasoline gallon equivalent basis.

The map to the right illustrates price differentials by state for natural gas relative to gasoline, based on differentials between natural gas and gasoline prices for each state (as opposed to the regional averages illustrated in Table 5). In this map, negative numbers represent prices for CNG lower than gasoline. As the map illustrates, CNG prices (per GGE) were favorable relative to gasoline in all states for which pricing data was reported, with the most favorable pricing found in states located in the Rocky Mountain, Midwest and West Coast regions.

Tech Note: Prices for CNG were provided by the individual stakeholders in gasoline gallon equivalents from the "price at the pump." It should be noted that the internal conversion factor between the physical quantities of gas delivered and gasoline gallon equivalent was not collected from each of the refueling stations. Regional differences in gas heat content relative to the internal pump conversion factor may change the price per gasoline gallon equivalent, but this report did not determine these differences.

Table 5. Compressed Natural Gas Average Prices by Region from Clean Cities Sources

	Natural Gas (CNG) Information Reported by Clean Cities (\$/GGE)		Regular Gasoline Information Reported by Clean Cities (\$/gal)	
	Average Price	Number of Data Points	Average Price	Number of Data Points
New England	\$2.53	28	\$3.76	27
Central Atlantic	\$2.19	104	\$3.41	54
Lower Atlantic	\$2.06	27	\$3.34	62
Midwest	\$1.87	72	\$3.32	138
Gulf Coast	\$2.02	29	\$3.11	40
Rocky Mountain	\$1.82	106	\$3.42	94
West Coast	\$2.31	103	\$3.78	101
NATIONAL AVERAGE	\$2.09	469	\$3.45	516

COMPRESSED NATURAL GAS (RELATIVE TO DIESEL)⁷

Table 6 shows average prices for compressed natural gas (CNG) for vehicle use, grouped by region, as well as conventional diesel fuel prices, as provided by Clean Cities representatives and supplemental sources. These prices were collected from across the country from Clean Cities coordinators, fuel providers, and other stakeholders on a voluntary basis. The CNG prices in Table 6 are based upon the same group of prices as for Table 5, but converted to a cost per diesel gallon equivalent basis instead of a cost per gasoline gallon equivalent, to compare directly with diesel prices.

Table 6. Compressed Natural Gas Average Prices by Region from Clean Cities Sources

	Natural Gas (CNG) Information Reported by Clean Cities (\$/DGE)		Diesel Information Reported by Clean Cities (\$/gal)	
	Average Price	Number of Data Points	Average Price	Number of Data Points
New England	\$2.82	28	\$4.09	33
Central Atlantic	\$2.44	104	\$3.78	47
Lower Atlantic	\$2.3	27	\$3.83	42
Midwest	\$2.09	72	\$3.81	87
Gulf Coast	\$2.25	29	\$3.78	18
Rocky Mountain	\$2.03	106	\$3.89	45
West Coast	\$2.57	103	\$4.11	78
NATIONAL AVERAGE	\$2.33	469	\$3.91	350

As Table 6 illustrates, CNG has a lower average price than diesel for all regions of the country, with the largest difference (\$1.86 per DGE) being in the Rocky Mountain region. On average, CNG costs about \$1.58 less than diesel on a per diesel gallon equivalent basis.

The map to the right illustrates price differentials by state for CNG relative to diesel, based on differentials between CNG prices and diesel prices for each state (as opposed to the regional averages illustrated in Table 6). In this map, negative numbers represent prices for CNG lower than prices for diesel. States not highlighted with a color did not have any CNG data points in the current report. As with the comparison to gasoline, CNG prices relative to diesel were favorable for all states for which pricing data was reported, with the most favorable pricing found in states located in the Rocky Mountain, Midwest and West Coast regions.

⁷ A total of 19 liquefied natural gas (LNG) price points were collected with an average fuel price of \$2.34 per gallon, or \$4.03 per DGE. Because of the small number of price points, this data is not reflected in the report.

ETHANOL (E85)

Table 7 shows average prices for an 85% ethanol/15% gasoline (E85) fuel blend, grouped by region, as well as regular gasoline prices, as provided by Clean Cities representatives. These prices were collected from across the country from Clean Cities coordinators, fuel providers, and other stakeholders on a voluntary basis.

As Table 7 illustrates, E85 has a lower average price per gallon than regular gasoline for each region, with the largest average differential (51 cents) being found in the West Coast region. On average, E85 is about 41 cents lower in price than regular gasoline on a per-gallon basis.

Table 7. Ethanol (E85) Average Prices by Region from Clean Cities Sources

	Ethanol (E85) Information Reported by Clean Cities (\$ per gal)		Regular Gasoline Information Reported by Clean Cities (\$ per gal)	
	Average Price	Number of Data Points	Average Price	Number of Data Points
New England	\$3.46	3	\$3.76	27
Central Atlantic	\$3.25	93	\$3.41	54
Lower Atlantic	\$3.11	47	\$3.34	62
Midwest	\$2.84	182	\$3.32	138
Gulf Coast	\$2.92	51	\$3.11	40
Rocky Mountain	\$3.11	65	\$3.42	94
West Coast	\$3.27	70	\$3.78	101
NATIONAL AVERAGE	\$3.04	511	\$3.45	516

The map to the right illustrates price differentials between E85 and regular gasoline by state, based on differentials between E85 and gasoline prices for each state (as opposed to the regional averages illustrated in Table 7). In this map, negative numbers represent prices for E85 lower than for gasoline, and positive numbers represent prices for E85 higher than gasoline, on a per-gallon basis. States not highlighted with a color did not have any E85 data points in the current report. As the map illustrates, the states with the most favorable E85 pricing were located in the Midwest region.

Tech Note: Ethanol (E85) contains about 30% less energy (BTUs) per volume than gasoline. Flexible fuel vehicles (FFVs) operating on E85 do not experience a loss in operational performance, but may experience a 25-30% decrease in miles driven per gallon compared to operation on gasoline. The appendix at the end of this report provides conversion factors for calculating E85 prices on a GGE and DGE basis. For a side-by-side comparison of available flexible fuel and other alternatively fueled vehicles, visit www.fueleconomy.gov.

PROPANE

Table 8 shows average prices for propane for vehicle use grouped by region, as well as regular gasoline prices, as provided by Clean Cities representatives. These prices were collected from across the country from Clean Cities coordinators, fuel providers, and other stakeholders on a voluntary basis. Some stations charge a different price for propane used in vehicles versus other uses. Where provided, the vehicle price has been included in this report.

Table 8. Propane Average Prices by Region from Clean Cities Sources

	Propane Information Reported by Clean Cities (\$ per gal)		Regular Gasoline Information Reported by Clean Cities (\$ per gal)	
	Average Price	Number of Data Points	Average Price	Number of Data Points
New England	\$3.28	16	\$3.76	27
Central Atlantic	\$2.87	55	\$3.41	54
Lower Atlantic	\$3.00	46	\$3.34	62
Midwest	\$2.67	59	\$3.32	138
Gulf Coast	\$2.80	47	\$3.11	40
Rocky Mountain	\$3.22	58	\$3.42	94
West Coast	\$3.06	88	\$3.78	101
NATIONAL AVERAGE	\$2.96	369	\$3.45	516

As Table 8 illustrates, propane prices are lower than gasoline in all regions of the country on a per-gallon basis. Overall, propane was about 49 cents per gallon less than gasoline, with the largest average price differential of \$.72 per gallon found in the West Coast region. Propane prices in this report are from both private fleet refueling stations and public refueling sites that can provide propane for vehicles and for other uses.

The map to the right illustrates price differentials between propane and regular gasoline on a per-gallon basis, based on differentials between propane and gasoline prices for each state (as opposed to the regional averages illustrated in Table 8). In this map, negative numbers represent prices for propane lower than gasoline, and positive numbers represent propane prices higher than gasoline. States not highlighted with a color did not have any propane data points in the current report. As the map illustrates, the most favorable prices were found in the Midwest and Central Atlantic regions, as well as some states in the New England and West Coast regions.

Tech Note: Propane contains about 25% less energy (BTUs) per volume than gasoline and about 35% less energy (BTUs) per volume than diesel. The appendix at the end of this report provides conversion factors for calculating propane prices on a GGE and DGE basis.

BIODIESEL BLENDS: B20

Table 9 shows average prices for B20, a 20% biodiesel/80% diesel fuel blend, grouped by region, as well as regular diesel prices, as provided by Clean Cities representatives. These prices were collected from across the country from Clean Cities coordinators, fuel providers, and other stakeholders on a voluntary basis.

As Table 9 illustrates, prices for B20 are between 2 cents and 26 cents per gallon higher than conventional diesel fuel in six regions. This quarter's data shows one region, New England, with B20 prices less than diesel.

On average in the U.S., biodiesel in a B20 blend costs about 11 cents more per gallon than conventional diesel fuel, based on current information.

The map to the right illustrates price differentials between B20 and diesel on a per-gallon basis, based on differentials between B20 and diesel prices for each state (as opposed to the regional averages illustrated in Table 9). In this map, negative numbers represent prices for B20 lower than diesel, and positive numbers represent B20 prices higher than diesel. States not highlighted with a color did not have any B20 data points in the current report. B20 had favorable pricing (per gallon) in a number of states located around the country.

Tech Note: B20 contains only about 2% less energy (BTUs) per volume than diesel. The appendix at the end of this report provides conversion factors for calculating B20 prices on a GGE and DGE basis.

Table 9. Biodiesel (B20) Average Prices by Region from Clean Cities Sources

	Biodiesel (B20) Information Reported by Clean Cities (\$ per gal)		Diesel Information Reported by Clean Cities (\$ per gal)	
	Average Price	Number of Data Points	Average Price	Number of Data Points
New England	\$3.94	8	\$4.09	33
Central Atlantic	\$4.04	31	\$3.78	47
Lower Atlantic	\$3.85	22	\$3.83	42
Midwest	\$3.83	35	\$3.81	87
Gulf Coast	\$3.83	7	\$3.78	18
Rocky Mountain	\$3.95	17	\$3.89	45
West Coast	\$4.26	52	\$4.11	78
NATIONAL AVERAGE	\$4.02	172	\$3.91	350

BIODIESEL BLENDS: B99/B100

Table 10 shows average prices for high-level blends of biodiesel (99% or 100% biodiesel with diesel fuel), grouped by region, as well as regular diesel prices, as provided by Clean Cities representatives. These prices were collected from across the country from Clean Cities coordinators, fuel providers, and other stakeholders on a voluntary basis.

The price of B99/B100 is higher than the price of diesel fuel on a per gallon basis in four of the regions for which data was collected, ranging from 29 cents higher in the West Coast region to 70 cents higher in the Central Atlantic and Rocky Mountain regions. In the New England and Gulf Coast regions, prices for B99/B100 were lower than conventional diesel, by 39 cents and 21 cents, respectively. In the Midwest, the average prices for B99/B100 and conventional diesel were the same. On average across the nation, the price of B99/B100 is about 27 cents per gallon higher than the price of regular diesel.

The map to the right illustrates price differentials between high-level biodiesel blends and regular diesel on a per-gallon basis, based on differentials between biodiesel and diesel prices for each state (as opposed to the regional averages illustrated in Table 10). In this map, negative numbers represent prices for these blends that are lower than diesel, and positive numbers represent prices for these blends that are higher than diesel. States not highlighted with a color did not have any high-level biodiesel blend data points in the current report. Where data was available for this report, prices for B99/B100 (per gallon) were most favorable in states located in the New England and Lower Atlantic regions.

Tech Note: B100 contains about 10% less energy (BTUs) per volume than diesel. The appendix at the end of this report provides conversion factors for calculating B100 prices on a GGE and DGE basis.

Table 10. Biodiesel (B99/B100) Average Prices by Region from Clean Cities Sources

	Biodiesel (B99/B100) Information Reported by Clean Cities (\$ per gal)		Diesel Information Reported by Clean Cities (\$ per gal)	
	Average Price	Number of Data Points	Average Price	Number of Data Points
New England	\$3.70	4	\$4.09	33
Central Atlantic	\$4.48	5	\$3.78	47
Lower Atlantic	\$4.02	17	\$3.83	42
Midwest	\$3.81	5	\$3.81	87
Gulf Coast	\$3.57	3	\$3.78	18
Rocky Mountain	\$4.59	3	\$3.89	45
West Coast	\$4.40	25	\$4.11	78
NATIONAL AVERAGE	\$4.18	62	\$3.91	350

COMPARISON OF PRICES OF THIS REPORT VERSUS LAST REPORT

Table 11, below, summarizes the average prices collected for this report by region, and compares them to prices collected in the Price Report from July, 2013. It should be noted that a portion of the price changes could be attributed to differing sample sizes and locations between the two reports.

Table 11. Comparison of Prices, Last Price Report versus Current Price Report

		Price for October 2013 Period	Price for July 2013 Period	Price Differential October vs. July
Gasoline (\$ per gallon)	National Average	\$3.45	\$3.65	(\$0.20) / (6%)
	New England	\$3.76	\$3.88	(\$0.12) / (3%)
	Central Atlantic	\$3.41	\$3.63	(\$0.22) / (6%)
	Lower Atlantic	\$3.34	\$3.49	(\$0.15) / (4%)
	Midwest	\$3.32	\$3.63	(\$0.31) / (9%)
	Gulf Coast	\$3.11	\$3.42	(\$0.31) / (9%)
	Rocky Mountain	\$3.42	\$3.55	(\$0.13) / (4%)
	West Coast	\$3.78	\$3.93	(\$0.15) / (4%)
Diesel (\$ per gallon)	National Average	\$3.91	\$3.91	\$0 / 0%
	New England	\$4.09	\$4.07	\$0.02 / 1%
	Central Atlantic	\$3.78	\$3.81	(\$0.03) / (1%)
	Lower Atlantic	\$3.83	\$3.82	\$0.01 / 0%
	Midwest	\$3.81	\$3.86	(\$0.05) / (1%)
	Gulf Coast	\$3.78	\$3.82	(\$0.04) / (1%)
	Rocky Mountain	\$3.89	\$3.86	\$0.03 / 1%
	West Coast	\$4.11	\$4.08	\$0.03 / 1%
Compressed Natural Gas (\$ per GGE)	National Average	\$2.09	\$2.14	(\$0.05) / (3%)
	New England	\$2.53	\$2.57	(\$0.04) / (1%)
	Central Atlantic	\$2.19	\$2.22	(\$0.03) / (2%)
	Lower Atlantic	\$2.06	\$2.01	\$0.05 / 3%
	Midwest	\$1.87	\$1.86	\$0.01 / 0%
	Gulf Coast	\$2.02	\$2.03	(\$0.01) / (1%)
	Rocky Mountain	\$1.82	\$1.82	\$0 / 0%
	West Coast	\$2.31	\$2.43	(\$0.12) / (5%)
Ethanol (E85) (\$ per gallon)	National Average	\$3.04	\$3.23	(\$0.19) / (6%)
	New England	\$3.46	\$3.58	(\$0.12) / (3%)
	Central Atlantic	\$3.25	\$3.44	(\$0.19) / (5%)
	Lower Atlantic	\$3.11	\$3.25	(\$0.14) / (4%)
	Midwest	\$2.84	\$3.15	(\$0.31) / (10%)
	Gulf Coast	\$2.92	\$3.13	(\$0.21) / (7%)
	Rocky Mountain	\$3.11	\$3.08	\$0.03 / 1%
	West Coast	\$3.27	\$3.40	(\$0.13) / (4%)

Clean Cities Alternative Fuel Price Report

October 2013

Table 11. Comparison of Prices, Last Price Report versus Current Price Report

		Price October 2013 Period	Price for July 2013 Period	Price Differential October vs. July
Propane (\$ per gallon)	National Average	\$2.96	\$2.73	\$0.23 / 9%
	New England	\$3.28	\$3.14	\$0.14 / 4%
	Central Atlantic	\$2.87	\$2.76	\$0.11 / 4%
	Lower Atlantic	\$3.00	\$2.83	\$0.17 / 6%
	Midwest	\$2.67	\$2.47	\$0.20 / 8%
	Gulf Coast	\$2.80	\$2.30	\$0.50 / 22%

	Lower Atlantic	\$4.02	\$4.05	(\$0.03) / (1%)
	Midwest	\$3.81	\$3.96	(\$0.15) / (4%)
	Gulf Coast	\$3.57	\$3.70	(\$0.13) / (3%)
	Rocky Mountain	\$4.59	\$4.45	\$0.14 / 3%
	West Coast	\$4.40	\$4.37	\$0.03 / 1%

COMPARISON OF PRICES BY REGION FOR PUBLIC AND PRIVATE REFUELING STATIONS

Table 12, below, summarizes the comparison of fuel prices included in this report, separated into averages for privately-owned stations or stations available only to selected fleets (private refueling stations) and stations open to the public (public refueling stations). Private fleet fueling stations can typically negotiate prices lower than retail public stations, if they are willing to commit to purchasing large quantities of fuel over an extended period of time. However, private fleet pricing can sometimes be higher than retail public stations if there are unusual circumstances (remote locations, sites that use very small quantities of fuel, or special contracts where unique billing, accounting, or fleet service management fees are rolled into the price of the fuel).

As with the other prices in this report, all of these averages are prices with state and federal taxes included, using the protocols outlined at the beginning of this document.

Table 12. Comparison of Prices by Fuel Type, Region, and Station Type

		<i>Private Refueling Station Average Price</i>	<i>Public Refueling Station Average Price</i>
<i>Gasoline (\$/gallon)</i>	<i>National Average</i>	\$3.45	\$3.44
	New England	\$3.64	\$3.77
	Central Atlantic	\$3.43	\$3.41

HISTORICAL ALTERNATIVE FUEL PRICES FROM PREVIOUS REPORTS

The graphs on this page illustrate the historical prices for the alternative fuels included in these reports (specifically natural gas, propane, ethanol (E85), and biodiesel) relative to gasoline and diesel. These graphs include prices collected as part of the current Price Report activity, which began in September 2005. Natural gas (in GGE), propane, and ethanol (E85) have been graphed against gasoline prices, while natural gas (in DGE) and biodiesel have been graphed against diesel prices.

ILLUSTRATION OF CONVERSION FACTORS FOR FUELS

The standard lower heating values for fuels from the Transportation Energy Data Book 30 are listed below.

	Lower Heating Value
Gasoline	115,400 BTU/gal
Diesel	128,700 BTU/gal
Compressed Natural Gas	960 BTU/cubic foot
Ethanol	75,700 BTU/gal
Propane	83,500 BTU/gal
Biodiesel	117,093 BTU/gal

Conversion factors to establish prices in dollars per gasoline gallon equivalent (GGE) are illustrated below, and were developed using the lower heating values outlined above. The conversion factors are derived in the manner shown in the graphic to the right.

In the case of CNG, prices are provided to us in GGE, so no conversion is necessary (the representative heating value of CNG is provided above as a reference). To convert a price from dollars per gallon to dollars per GGE, multiply the price per gallon of the alternative fuel by the conversion factor.

	Conversion factor to GGE
CNG	1.00
Ethanol (E85)	1.41
Propane	1.38
Biodiesel (B20)	0.91
Biodiesel (B100)	0.99

Conversion factors to establish prices in dollars per diesel gallon equivalent (DGE) are illustrated below, and were developed using the lower heating values outlined above. To convert a price from dollars per gallon to dollars per DGE, multiply the price per gallon of the alternative fuel by the conversion factor.

	Conversion factor to DGE
CNG (in GGE)	1.12
Ethanol (E85)	1.58
Propane	1.54
Biodiesel (B20)	1.02
Biodiesel (B100)	1.10

ACKNOWLEDGEMENTS

The authors would like to acknowledge all of the contributors from the Clean Cities community who have provided prices for this report; we sincerely appreciate your continued dedication to the success of this report. The authors would also like to acknowledge the continued support of DOE for developing this report.

WOULD YOU LIKE TO PARTICIPATE?

If you would like to provide prices for alternative fuels in your region and be part of the data collection effort for this report, or if you have any questions, please contact:
